ANALYTICAL CHEMISTRY.

A Manual of Chemical Analysis, Qualitative and Quantitative. By G. S. Newth. Pp. 462. (London: Longmans, Green, and Co., 1898.)

A Laboratory Guide in Qualitative Chemical Analysis. By H. L. Wells, M.A. Pp. 180. (New York: Wiley and Sons. London: Chapman and Hall, Ltd., 1898.)

A Short Course in Inorganic Qualitative Analysis. By J. S. C. Wells, Ph.D. (New York: Wiley and Sons. London: Chapman and Hall, Ltd., 1898.)

IT is now becoming generally recognised that chemical analysis is a subject that may be looked at, taught, and practised in two ways—as an art, or as a science. No doubt it should be both, and always has been both with chemists properly so-called; but it is sad to think of the time, trouble and money that have been expended during the last thirty years in disseminating a smattering of the analytical art on the supposition that education and even British industry would be thereby furthered.

The demand for a practical chemistry that could be easily scheduled, that should not be too elaborate, and that could be examined and controlled by sending out packets of powders and getting back packets of papers, has contributed, doubtless, more than anything else to the degradation of chemical analysis. At the same time it must be admitted that chemical analysis as a science suffered seriously by the abolition of the ideas and notation of the dualistic theory. Before then the current names and formulae were at least consistent, and the writing of equations could be conducted on comparatively simple general principles. Even now there are probably few chemists who would calculate the oxidising value of potassium permanganate in reference to ferrous sulphate, otherwise than by dualistic conceptions and formulae. The hopeless confusion arising over the old terms *acid*, *base* and *salt*, and especially *basic salt*, in their modern use, must be known to every teacher.

To those who in recent years have protested against chemical analysis as an introduction to practical science it has been objected that analysis, when properly taught, is a highly educative subject. But this has never been disputed; the point is that analysis is far too high a science and too difficult an art for young boys, and that a little proficiency in the art of "taking a solution through the chart" has, practically speaking, been the only attainable outcome of a positive kind, whilst the habits of mind and manipulation usually engendered have been lamentable.

The tide is happily with the reformers, and the improvement that has taken place within the last ten years in school science is one of the most remarkable and gratifying of the numerous signs now evident that a more rational and humane spirit is pervading British education.

For those who wish to make a serious study of chemistry, chemical analysis has still to be taught, and how to teach it best, is a question which may perplex the most thoughtful teacher. The fundamental difficulty is that there appears to be no thin end to the wedge. If the subject is to be taught scientifically—that is to say, if the reactions on which analysis is based are to be elucidated as they arise—the student is at once thrust into a thicket of ramifying facts in which he will find his way with difficulty. Suppose he begin with the reactions of the silver group, he is at once among the mercuramines; should he begin at the other end, there are the platinichlorides and acid tartrates. The student, in fact, who is to learn analysis scientifically at the first attempt, requires a fair knowledge of chemistry to begin with. The choice lies between devising some extended practical work, beyond the mere preparation of gases, as a preliminary to analysis, or making the student, as he might put it, "do analysis" more than once. In the last case, the analytical operations are not comprehended to their inmost parts in first traversing the course, but a preliminary survey is obtained, and the student learns something, at least, about a great many substances and reactions. It is, after all, something to know the mere outside of things in chemistry. The difficulty, however, is to secure the *da capo* or cud-chewing process which is essential to the success of this scheme. It is not easy to convince the half-informed of

their ignorance. No doubt, the best way to approach analysis is through preliminary practical work in which typical substances are prepared by typical reactions, and subjected to a careful qualitative and quantitative study; but no one has yet given a really good lead in this direction, though several books of inorganic preparations have appeared in recent years.

Sooner or later the serious student of chemistry must enter upon the systematic study of analysis, and the selection of a good handbook becomes an important matter. It has been the habit for writers on analysis to confine themselves almost entirely to the technique of the subject, and among the scores of books written a fair number might be named as trustworthy guides in the processes of qualitative and quantitative analysis. At the head of these stands the well-known work of Fresenius—a monument of industry and care. It must be recognised, however, that Fresenius' book is essentially an analytical dictionary. If it be an object in the teaching of analysis—and it is surely, for the general student, the chief object—to make the learner familiar with the philosophy of the subject, the use of Fresenius and the smaller versions of Fresenius must be supplemented by something else, either in the way of oral teaching or literature. The circumstances of few laboratories permit of the constant personal supervision which is necessary to keep an analytical student straight on the theoretical side of his work, and thus the possession of a book which really grapples with the chemistry of analytical reactions becomes indispensable. It is, however, only recently that a book adequately fulfilling this purpose has appeared in the English language, though a little-known manual published by the late Prof. Dittmar, in 1876, deserves respectful mention. In Germany (and doubtless in Russia) for many years Menschutkin's book has occupied the place in question. Menschutkin does not pretend to be an exhaustive compendium of analytical processes; it contains no tables; it lays down no laws for the treatment of a solution containing a limited number of acids or bases; yet Menschutkin has the stamp of individuality and real science, which make it not unworthy of companionship with Mendélejeff's Principles. It was the only book on analysis which Bunsen, who had a horror of the analytical "Bradshaw," would allow to appear in his laboratory. It is to be hoped that through its English translation the book has become better known in this country.

One more type of work on analysis, and only one, can be mentioned. Ostwald's "Scientific Foundations of Analytical Chemistry" is a book *sui generis*. The view taken of this book will depend entirely on whether the reader finds the preamble proven. If the ionic theory of solution be accepted, there can be no doubt of the remarkable coherence and symmetry of Prof. Ostwald's adaptation of it to the facts and processes of analysis. The book is well worth the attention of any one who may have lightly taken up a mere prejudice against the ionic theory.

Of the books at present before us, two are of considerable interest as being out of the common style. Mr. Newth, who is well known as the author of a book of lecture experiments, and one on inorganic chemistry, both characterised by many excellent features, has now produced a manual of analysis which is no less satisfactory. It is written much in the style of Menschutkin, that is to say, it is thoroughly explanatory. At the same time there is no lack of plain practical directions for the conduct of analytical work. The book gives evidence throughout of having been written by a skilled analyst and a thoughtful chemist, whilst the frequent asides—sometimes beseeching, sometimes scornful—show that the author has tasted the sorrows of a teacher of analysis. Beginning with a chapter of preliminary manipulative exercises, the book proceeds to detail and explain the reactions of the metals in the order of the analytical groups. Two chapters follow on the conduct of a qualitative analysis and the statement of results. The second part of the book deals with quantitative analysis, including electrolytic analysis, gas analysis and organic analysis, concluding with a section on miscellaneous physico-chemical determinations. This brief summary of contents will, of course, give little idea of the real character of the book, yet it is impossible to enter minutely into either explanation or criticism of a work so full of details. The least satisfactory part is the first chapter dealing with the important matter of manipulation. In the first place it must be remarked that the essentials of manipulation should have been learned long before the systematic study of analysis is commenced, and a student who is at all ready to enter upon the second chapter of Mr. Newth's book will very probably resent the instruction to mix hydrochloric acid and charcoal in order to see how the charcoal may be filtered off and washed. Such elementary instructions are doubtless useful in their place; but their juxtaposition with chapters on systematic analysis only tends to confirm the practice of plunging students of practical chemistry prematurely into analytical work. It would at least have been better if this intention had been disclaimed. The instructions themselves also call for some comment. No recommendation is made of the filter-pump for qualitative analysis, an omission which, in the opinion of the present writer, is very regrettable. It is true that in the hands of a careless and uncontrolled student a vigorous filter-pump is a source of moral degradation, but, in other hands, it is, with limited exhaustion, perhaps the chief aid to dispatch, neatness, and even accuracy. The instructions given by Mr. Newth for evaporation, neutralisation, the use of borax beads, and the removal of precipitates seem to show that many of Bunsen's helpful artifices are still unknown in England. Other useful things which do not seem to be described by Mr. Newth, are the Gooch crucible and the perforated disc porcelain funnel. The writer would also here recommend the process of separating barium, strontium and calcium by means of nitric acid, described by Dr. S. G. Rawson in the number of the *Journal* of the Society of Chemical Industry for last February.

An addition that may well be made to a future edition is a plain statement about the rational use of figures in quantitative analysis. It is astonishing how little attention is paid by chemists to the significance of figures in the statement of an analytical result, and how seldom students are taught to let their recorded numbers bear a

proper relation to the accuracy attainable, even with perfect manipulation, in any given process. It is the commonest thing to find a pretension to accuracy of 1 part in 1000 where 1 in 50 would hardly be justified.

Mr. Newth does not introduce the ionic theory into his explanations of analytical reactions. It is not difficult to understand reluctance to embrace a theory which is still young and still the object of adverse criticism. At the same time it seems a great pity that a writer on analysis should leave the student in ignorance of what, according to a large number of eminent chemists, is the real key to the chemistry of analysis. The ionic theory need not have been woven into the fabric of the book; but it, at least, deserved a chapter and a fair hearing.

Whilst a few defects are to be noticed in the book, it is right to add that the merits are much more conspicuous; and it may be said, on the whole, that Mr. Newth's account of analysis is wide in scope, exact in detail, and particularly luminous in exposition. If it is used conscientiously by duly prepared students, it will teach them a great deal of chemistry.

Prof. Wells's book is written on somewhat different lines, yet is characterised, like Mr. Newth's, by the attention paid to the explanation rather than the mere description of reactions. Prof. Wells, who has charge of the teaching of analytical chemistry and metallurgy in the Sheffield Scientific School of the Yale University, is evidently deeply impressed with the feeling that students tend to do their analytical work in a mechanical way, taking merely marching orders from their text-books. Instead, therefore, of telling the student anything about the metallic chlorides, the author contrives that the facts shall be *discovered* by such instructions as:

"Find by experiment which of the twenty-seven solutions give precipitates when a few drops of hydrochloric acid, HCl, are added to 1 or 2 cc. in a test-tube. Write the equations of the reactions and remember the facts observed in this experiment as well as in those that follow. Why are no precipitates produced in the solutions containing chlorides?"

The directions continue in the same strain. It must be observed that the student does not proceed on a natural voyage of discovery. At every port he opens another sealed order, and takes the directed course wherever it may lead. The value of this method of teaching analysis is open to serious doubt. The student is asked to perform twenty-seven experiments, of which all but three are, practically speaking, blanks. The present writer's experience is that operations of this kind pall intolerably upon a self-respecting student. We surely have here a case where a wrong sacrifice is made to pedagogic theory. In the early stages of education it is no doubt hardly possible to pay too much attention to method. Whilst habits of mind are being formed, and pupils are young and docile, much may be permitted in the name of method; but a period arrives when the leading strings must be relaxed. As soon as a system of teaching is felt by the pupil to be a system, it is apt to lose its value, and to engender the resentment which every one feels on discovering that he is being manoeuvred. The present writer has had experience of the unintelligent student of practical chemistry, and has tried Prof. Wells's device, among others. The result has not been at all encouraging. The fact is, that by the time a student is fit to begin the study of analytical chemistry he should be fit to avail himself of straightforward explanations. If he is not fit, strategy will do but little to mend matters. Prof. Wells, however, thinks differently after fourteen years' teaching and it may be that things are different in America.

Whilst offering this general criticism of Prof. Wells's system, it is right to add that the book is wholly good in its scientific tendency, and that it contains abundant evidence of the writer's experience and grasp of analytical chemistry. The injunction that the student is to construct his own tables of separations is much to be commended. The second part of the book deals with theory; it embraces the ionic theory, and explains the phenomena of analysis from that point of view. The explanations are, it is to be feared, too brief and sketchy to be of much use. They have a somewhat high-sounding logical form, but do not always convey much substance.

"There is a direct connection between the formation of precipitates and insolubility. A compound which is readily soluble in the liquid that is present *cannot* form a precipitate in the presence of a sufficient amount of that liquid."

This surely was unnecessary.

The chapter on equations is clear and useful. The third part of the book gives an account of the properties of the inorganic radicals in alphabetical order, and does not purport to be more than a condensation of Fresenius. It contains a summarised statement of what the student is meant to have learned for himself by working through Part i.

Two "appendixes" to the book, consisting of eighteen pages of labels, seem very unnecessary.

The third book before us is also of American origin. It is intended for engineering students, though there is no evidence of this special destination in the text. In so far as the reactions are explained with fair completeness, it is in advance of the customary analysis book. The distinctive feature is to be found in a number of large tables plotting an outline of reactions which occur in the separation of the members of a group. By reference to the tables it is possible to see what is the maximum number of substances in any particular precipitate or filtrate. Thus precipitate 35 may contain $BaCO_3$, $SrCO_3$, $CaCO_3$, whilst filtrate 35 may contain $MgCl_2$ NH_4Cl, $NaCl$, KCl, $BaCl_2$ and $CaCl_2$ in traces, NH_4OH, $(NH_4)_2CO_3$. The author states that these tables have been found of much benefit to the student.

In the beginning of the book we find the statement that "in inorganic chemistry the bases comprise the metals, and the acids the non-metallic elements (with a few exceptions)"; a little later—"all acids contain hydrogen, which hydrogen is replaceable by a base"; and lastly—"bases have properties just the reverse of acids. Among the inorganic compounds they usually consist of hydroxyl in combination with a metal. Their chief characteristic is their power of uniting with acids to form neutral compounds." Could any better justification be found for the remark, made early in this article in reference to the dire effects of lingering dualistic terminology?

ARTHUR SMITHELLS.

RESEARCHES ON MEDUSAE.

The Cubomedusae. By Franklin Story Conant. (Memoirs from the Biological Laboratory of the Johns Hopkins University, vol. iv. No. 1.) Pp. xvi + 61, and plates. (Baltimore: Johns Hopkins Press, 1898.)

IT is one of the characteristics of some of the more important American Universities that they advance knowledge, employ the best of their young graduates, and at the same time add to the treasures of their museums by equipping expeditions to explore unknown regions, both of sea and land. In this way the archaeology, ethnology, geology, palaeontology, and marine zoology of Central and North America have all benefited largely; and the results of these College expeditions are to be seen in several of the Transatlantic Museums and Universities.

Last year (1897) was unfortunately most disastrous to the marine biological expeditions of two of the leading American Universities: Columbia at New York, and the Johns Hopkins at Baltimore. The Columbia University Expedition to Alaska was wrecked on the return voyage by running on the West Devil rock in Dixon entrance, the steamer sinking almost at once in deep water, and the party barely escaping with their lives (one of them, young Mr. B. B. Griffin, has unfortunately died since), while all their collections, notes, drawings, theses, and other property were lost. The Johns Hopkins Expedition to Port Antonio, in Jamaica, had even a more tragic termination. Prof. Humphrey, the leader of the expedition, died of yellow fever after a few hours' illness the day (August 17) they were to have sailed for home. Dr. Conant, the second in command, and Dr. Clark considered it their duty, under the circumstances, not to leave. Clark was then taken ill and recovered; but when they eventually sailed from Port Antonio, on September 6, Conant became ill on the second day at sea, and died on September 13 in Boston.

The present volume consists of Dr. Conant's researches on the Cubomedusae completed, and accepted by the Johns Hopkins University as a dissertation for the degree of Doctor of Philosophy, just before the author sailed on the fatal expedition to Port Antonio, and now published as a memorial by his friends, fellow-students and instructors at the University. Dr. Conant had been with the Johns Hopkins marine laboratory party at Jamaica in June 1896, and the discovery then of two new species of Cubomedusae in Kingston Harbour led him to the further study of the group. Cubomedusae are comparatively rare jelly-fish, and are of morphological interest because of the relatively high degree of development attained by their nervous system and sense-organs. After a systematic review of the position of his new species (one of them the type of a new family), Dr. Conant gives an excellent account of the anatomy and histology, with a specially full description of the nervous system and of the highly-developed eyes and associated sense-organs. Eight clearly drawn plates, nearly all the figures being from drawings by the author, illustrate satisfactorily this monograph, which is of special interest, first as giving an account of a rare group of medusae, and secondly because of its sad associations. Dr. Conant was a talented and high-souled young zoologist, who seems to have sacrificed his life to a sense of duty and devotion to others.

During this last stay in Jamaica, Conant seems to have been working largely on physiological problems especially of the sense-organs, such as the action of retinal pigment-cells under the influence of light and darkness; and also on the embryology of the Cubomedusae. We are glad to learn from Prof. W. K. Brooks, that Conant's notes are so full and so advanced that he hopes to be able to have them completed and published before long.

W. A. H.

OUR BOOK SHELF.

Special Report on the Beet-Sugar Industry in the United States. Pp. 240. (Washington: Government Printing Office, 1898.)

FOR some time the United States Department of Agriculture has been instituting and directing experiments to ascertain where sugar-producing plants can be grown most profitably. The present volume contains the results of this investigation so far as concerns the beet-sugar industry. It is divided into two parts, one part consisting of the report of the chemist of the Department, Dr. H. W. Wiley, while the other consists of the report of the field agent, Mr. C. F. Saylor, who has personally visited and examined the plantations and factories concerned in the beet-sugar industry in a large number of districts.

The facts and figures presented in the volume justify the attention which the Department of Agriculture has given to the development of this important industry. How widespread is the interest taken in the subject may be judged by the fact that 150,000 copies of a farmers' bulletin upon sugar-beet were applied for last year, and 60,000 copies of the present report have been printed for distribution.

Numerous packets of sugar-beet seed were sent to different parts of the United States last year with the object of obtaining information as to the regions in which the sugar industry is most likely to succeed. There are, however, such great differences in soils and climatic conditions in the United States, that seeds which are suitable for one locality may not succeed in another. Dr. Wiley therefore points out that the experiments which the Department of Agriculture has conducted for several years in the analysis of beets, and the delimination of areas suited to beet culture, require now to be supplemented by a more rigid scientific attempt to develop beets of characteristics best suited to the various localities.

The opinion of Mr. Saylor upon the industry is decidedly optimistic. He says: "There is no doubt that the United States has a wide and varied extent of land that will successfully grow high-grade beets, that the enterprise of the people of this country will appreciate this fact, and that in a short time all the sugar consumed in this country will be furnished by our own people." Whether this prediction will be fulfilled during the next few years remains to be proved; but, in any case, the Department of Agriculture is doing its best to educate and assist the farmers who cultivate lands upon which the sugar-beet can be successfully grown.

Traité d'Algèbre Supérieure. Par Henri Weber. Traduit de l'allemand sur la deuxième édition par J. Griess. Pp. 764. (Paris: Gauthier-Villars, 1898.)

THIS is a translation of the first volume of the second edition of Prof. Weber's "Lehrbuch der Algebra," and will doubtless be welcome to those who are more familiar with French than with German. The translation appears to be trustworthy, although a few misprints have crept in here and there which are not in the original; thus on pp. 71, 72, the indices $a_1, a_2 \ldots a_m$ should be replaced by

$\mu_1, \mu_2 \ldots \mu_m$, and on p. 150 $f(x)$ has been printed instead of $f'(x)$. On p. 73 the phrase "en outre" is an imperfect equivalent for "wir setzen noch," and is likely to make the reader suppose that the symbol $\Phi(x, \xi)$ has been already defined. The handsome appearance of the volume, and the excellence of the printing, fully maintain M. Gauthier-Villars' high reputation.

The first edition of the "Lehrbuch" was reviewed in this journal at considerable length, so that it is unnecessary to give here any detailed account of the contents of this volume. Prof. Weber has introduced various improvements in detail, and added, amongst other things, an account of Lagrange's interpolation formula, and of Hurwitz's very interesting researches on Sturm's theorem. The extreme value and originality of the treatise become more evident the more carefully it is studied; the appearance of this translation, as well as that of the second edition at home, indicates that its great merits are being duly appreciated. G. B. M.

A Manual of the Grasses of New South Wales. By J. H. Maiden. (Sydney: Gullick, 1898.)

BROUGHT out under the authority of the Minister for Mines and Agriculture for New South Wales, the Government botanist publishes a very useful account of the grasses of the Colony. The number of species indigenous to the Colony is stated at 196, comprised in 56 genera. These numbers may be compared with the 95 species belonging to 48 genera reckoned by Hooker as natives of these islands. Under each species, in addition to the technical diagnosis, the vernacular names are given, with a reference to the published figures; the habitat and range of the species, and an account of its value for fodder and for other purposes. Then follows a key to the genera, and under each genus a key to the species. In the case of a number of the more useful or more common species, full-page illustrations are given. The volume is a very useful and valuable one; but, considering its purpose, it strikes us that its practical value would be increased by either a general description of the flower of grasses, or a glossary of technical terms; unless indeed, Australian farmers are much better acquainted than our own with botanical terminology.

Manuel de l'Explorateur. By E. Blim and Rollet de l'Isle. Pp. vii + 260. (Paris: Gauthier-Villars, 1899.)

THE object of this volume is to provide travellers in little-known regions with information which will enable them to record particulars of service to geography concerning the land traversed. In the first chapter the methods are described for determining and representing approximately the route followed and the details of the surface, using a prismatic compass and an aneroid. The astronomical observations required to define positions along the route are then explained, and it is shown how the combination of these observations with the rough survey enables an approximately accurate representation of the journey to be laid down. The determination of heights and distances by levelling and triangulation are described in the third chapter, for the instruction of explorers who wish to make a detailed study of particular districts. The two remaining chapters deal with systems of projection for the conversion of the observations to maps, and the choice and transport of the instruments referred to in the text. The sextant is not included among the instruments, the astronomical observations being made with the theodolite instead. No instructions are given as to what to observe in natural history, geology, anthropology, or other sciences; hence, the volume is not to be compared in value with the "Hints to Travellers" published by the Royal Geographical Society. Nevertheless, as a clear and very elementary manual on surveying and practical astronomy for travellers who explore without having received a preliminary scientific training, the book may prove of service.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Heredity and Fertility.

AS Prof. Karl Pearson in his paper "On the Law of Ancestral Heredity," published in the *Proceedings* of the Royal Society, alludes to an investigation which he has apparently commenced into the inheritance of fertility in man, it may be of interest now to publish one which I completed some years ago, but which for various reasons has not appeared in print.

The problem to be solved was:—Do marriages of heiresses prove more or less fertile than ordinary marriages? The first desideratum was of course to get a practically homogeneous class from which to obtain the necessary data. The families enrolled in "Burke's Peerage and Baronetage" sufficed. Taking the volume for 1892—just published when this investigation was commenced—there were in it of the present generation 265 ordinary or non-heiress marriages which had produced an average of 3·8 children per marriage, forty-eight of which, or 18·5 per cent., were absolutely sterile.

Now an heiress, so called in "Burke," may be considered of the same class as an only child. Hence, taking care that both parents lived long enough after the birth of their first child to have had others, I extracted all the marriages of heiresses and female only children that occurred in "Burke" for the present generation, with the addition of a considerable number from the past generation contained in "The Lineage." There resulted:—243 marriages, averaging 3·74 children per marriage and 11·9 per cent. marriages absolutely sterile. These figures show that there is practically no difference in the fertility of ordinary marriages—3·8 per marriage—and the 3·74 fertility of heiresses and only children: the small difference of six-hundredths per cent., on so small a number as 250 marriages, being well within the ordinary limits of error. It implies that with greater numbers the results would probably be similar. Not so, however, when we come to consider the number of marriages which are absolutely sterile, for these are so much fewer with the only children marriages—6·6 per cent.—that we must say when they are fertile they are more fertile than the others.

But the problem may be attacked from the other side. If female members of the smallest families possible tend to bear fewer children than the female members of families of ordinary size, the female members of large families would tend to bear large families. Is this so? With a much greater amount of labour than would be imagined, I extracted from the same work some marriages of ladies who were members of families of five or more, *i.e.* had in each case four or more brothers or sisters, with the result that 250 marriages averaged 4·25 per marriage with 13·6 marriages quite sterile.

Summarising, we get then ladies of small families average 4·06 children per marriage, 11·1 per cent. marriages being quite sterile.

Ladies of ordinary families average 3·8 per marriage, 18·5 quite sterile.

Ladies of large families average 4·25 per marriage, 13·6 quite sterile.

This shows that the more contrasted the ladies are as regards number of brothers and sisters, the more nearly allied are the numbers of their children and the relative amount of absolute sterility. A conclusion tending to show that the cause under investigation is not a *vera causa*.

Does the female influence show itself in a change in the proportion of male to female children, assuming of course a chance distribution of the husbands as being members of small, ordinary, and large families?

	Sons.	Daughters.	Total	S. to 100 D.	Sterile.
243 heiress and only-child marriages	492	414	906	107 sons	11
265 ordinary marriages ...	514	528	1042	97 sons	18·5
250 large family marriages	553	510	1063	108 sons	13·6

The same result as before—the most contrasted classes give the most similar results.

If heredity has anything to do with this matter, which so far seems improbable, it may arise from the other side—the father's. Hence I extracted marriages of only sons, of sons of ordinary

marriages, and of sons who had four or more brothers or sisters, and found that :—

	Children per marriage.	Sons to 100 Daughters.	Sterile.
191 only sons	4·09	116 sons	8·4 per cent.
265 sons of ordinary families	3·8	97 sons	18·5 ,,
500 sons of large families..	3·8	110 sons	12·4 ,,

These results point rather to the conclusion that could have been surmised: only sons being usually better off, have no reason to restrict the size of their families, as is so often necessary where a fortune has to be divided among many, and hence they have larger families.

Adding the three separate parental classes together, we have :—

	Sons.	Daughters.	Total.	Per marr.	Sons to 100 Daughters.
434 F. and M. only children	912	776	1688	3·89	117
265 F. and M. ordi- families	514	528	1042	3·9	97
750 F. and M. large families	1558	1424	2982	3·98	109
			5712		

Which shows that the number of children per marriage is so nearly similar that with a larger number of marriages to deal with they would probably be the same. Comparing the figures in the last column brings forth the most curious result of the investigation, that the marriages of members of ordinary sized families have a smaller proportion of sons to daughters than in the case of the other marriages.

The size of the families of the various classes dealt with may prove of interest, although nothing of great importance can apparently be drawn from the figures. The table contains the percentage of children per hundred marriages :—

Number of family.	Sterile. 0	1, 2	3, 4	5, 6	7, 8	9 & over.
Marriages of—						
Only female child ...	11	26	26	24	9	4
Only male	9	30	25	15	12	9
Ordinary	18	19	24	18	11	10
Daughter of large families	14	23	16	19	12	14
Son of large families ...	12	26	25	18	10	8
Total	64	123	117	95	54	42
Average	12·3	10·2	9·7	8	4·5	3·5

And, now, what are the final results to be drawn from the foregoing analysis? That, as a matter of fact, there is in no case a difference of sufficient magnitude to enable us to say that the fertility of either male or female in the human race is in any way correlated to the fertility of their fathers or mothers, and *a fortiori* correlated to the fertility of their grandparents.

Churchfield, Edgbaston. F. HOWARD COLLINS.

"A Short History of Scientific Education."

IN Sir Norman Lockyer's address, under the above title, reprinted in NATURE of October 13, he is reported to have said: "Before the Reformation the universities were priestly institutions, and derived their authority from the Popes. The universities were for the few; the education of the people, except in the various crafts, was unprovided for. The idea of a general education in secular subjects at the expense of the State or of communities is coeval with the Reformation. In Germany, even before the time of Luther, it was undreamt of, or rather, perhaps, one should say, the question was decided in the negative." . . . "With the Reformation this idea spread to France."

The whole passage seems to have been taken from that travesty of "The History of Pedagogy" compiled by Dr. Gabriel Compayré (compare pp. 114-115 and 120), and it is unfortunate that Sir Norman Lockyer should have followed so untrustworthy a guide.

For the statements contained in the above-quoted sentences are in direct opposition to the facts as ascertained by the best authorities in the matter. It is quite true that education owes much to the bishops and monks of the centuries before the Reformation, for it was in the episcopal seminaries, which formed a part of the bishop's own household, and in the great monastic schools, such as those of Cluny, Bec, St. Gall, and numerous others, that the torch of learning was kept alight in the troublous times when the laity were mostly fighting to resist the incursions of barbarians, or warring one with the other.

The priestly influence was therefore an influence for good. More than this, such Popes as Innocent III., Honorius III., Benedict XII., Gregory IX., Urban IV., to name no others, deserve the gratitude of mankind of all ages for their persevering efforts to improve the state of learning in the schools and universities of their times. Sir Norman Lockyer tells us that the "universities were for the few." How is this statement to be reconciled with the fact that students flocked to the universities in the days before the Reformation in multitudes so great, that we find it reported, that in the thirteenth century some ten thousand scholars attended the classes of the University of Bologna at one time, with another forty thousand at Paris, and thirty thousand at Oxford, while at Bordeaux a single college boasted of upwards of two thousand scholars. Even allowing that the numbers are exaggerated, it is indisputable that in this century the universities were crowded with students. Nor were these scholars all clerics, nor yet the sons of the nobles and well-to-do citizens, but mostly poor men—a scholar and a poor man being almost synonymous terms. Does not our own Chaucer describe the Clerk of Oxenford as "full hollow and threadbare?" And this, too, at a period when printed books were either altogether wanting or were a rarity. The number of universities founded in Europe in pre-Reformation days has been reckoned as sixty-six.

And what is true of universities is true also of elementary and grammar schools. In this connection, the first essay of John Charles Tarver's collection, "Debateable Claims," is worth referring to. "Fifty years ago," he writes, "the Reformation was popularly regarded as the very first beginning of enlightenment. Up to that time a crass and brutish ignorance was supposed to have prevailed . . . Since the middle of this century this view of our history has been considerably modified . . . How were the middle classes taught before the Reformation? The popular view is that they were not taught at all till Henry VIII. and his children, especially Edward VI., reserved something from the spoils of the Church endowments for grammar schools. A more enlightened view holds that incidentally the monasteries themselves were teaching establishments, and especially that the friars were not only preachers, but teachers . . . we should hardly have expected to find that the period of the Reformation was a period of indifference to schools; it was more than that, it was a period when schools were suppressed" And further on: "Again, the Reformation in its later stages was distinctly an upheaval of ignorance: the value of the old methods of teaching was not understood; 'the baser sort,' armed with the text of the Bible, thought all other learning superfluous; they regarded it, as classical learning is regarded by the scientific smatterer of to-day, as antiquated and superstitious. In Germany, according to Dr. Scherer, this attitude of mind contributed to the Counter-reformation; for contempt of learning having destroyed the teachers, when in the fulness of time the want of them was felt, the Jesuits were ready to take their place." In Mr. Leach's "English Schools at the Reformation," we learn that in England about the year 1546 there was one grammar school for every 8000 people, instead of one for every 23,000, as was the case in 1865; so that, at least in England, it is not correct to state "that the education of the people was unprovided for."

And what is true of England is true of other countries. As a set-off to the reference made by Sir Norman Lockyer to Luther's laudable endeavours in the cause of free education for the people, let us take the following quotation from a decree drawn up in the days of the Anglo-Saxons. "Mass-priests shall always have in their houses a school of learners; and if any good man will trust his little ones to them for lore, they shall right gladly receive and kindly teach them. . . . They shall not, however, for such lore, demand anything of the parents, besides that which the latter may give of their own will." This decree first appears in the Council of Vaison, and re-appears in the acts of several Councils of England, France, and Italy: for instance, in the Carlovingian Council of Orleans, and in the Constitutions of Vercelli. The request of the States General of Orleans in 1560 to Francis II., quoted by Sir Norman Lockyer, is therefore nothing new in the matter of free education. In addition to the Constitutions of Vercelli, those of Dado of Verden, and Heraclius of Liege, ordain the establishment of "little" or parochial schools, wherein poor children of both sexes, about the age of seven years, are to be taught gratis. That free

schools existed in England before the Reformation, as for instance those at Wisbech, Week St. Mary, Wimborne, Darlington, and Chipping Campden, appears from Mr. Leach's researches before referred to (pp. 110–114). In fact, the very idea of receiving payment for teaching was scouted until the introduction of secular teachers about the beginning of the eleventh century.

And yet Sir Norman Lockyer speaks of "the iron heel of priestcraft"—an ugly word—as arresting the "new spirit" presumably of free education of the people. Nor is his uncomplimentary reference to the Jesuits in France more according to facts. However what the Society of Jesus has effected for the cause of education, both literary and scientific, is too patent to any unbiassed student of the history of education to need discussion. Moreover, I should be needlessly occupying space in this journal. A. L. Cortie.

Stonyhurst College, October 23.

Organic Variations and their Interpretation.

I hope you will allow me to correct two serious errors in Prof. Weldon's reply to my criticisms.

I was never foolish enough to assert, as he implies that I did, that the theory of natural selection attempts to answer the question whether modifications originate accidentally or not. I said that this was the question between the adherents of the theory and its opponents. I quite agree with Prof. Weldon that the theory of natural selection does not involve a theory of the origin of variations. For that reason it is not by itself a theory of evolution.

Prof. Weldon asserts that I said there was no evidence of the entrance of fine mud into the gill-chambers of crabs during life. I said, or wrote, nothing of the kind. He found china clay in the gill-chambers of the individuals which died in his experiments, and I pointed out that this was no proof that the crabs had died because their branchial apparatus was unable to keep out the particles of clay. The clay was not found in the gills of the survivors, and he inferred that they owed their survival to more efficient filtration, due to their relatively narrower frontal breadths. I merely pointed out that the inference was not valid because the dead crabs had been in the muddy water after death, while the survivors were killed after removal.

I do not admit that Prof. Weldon has successfully vindicated his evidence or his conclusions against my criticisms; but as you, Sir, are unable to allow me any more space, I must thank you for printing my first letter, and leave further discussion of the matter for some other opportunity.

Penzance, October 22. J. T. Cunningham.

SCIENTIFIC EDUCATION IN RURAL DISTRICTS.

Among the problems of technical education which County Councils have had to face, the most difficult is the bringing home of the importance of scientific training to those engaged in agriculture and in rural industries generally. A study of the results achieved in the various counties very clearly brings out the fact that while considerable progress has been made in manufacturing centres where the practical bearing of science is more or less obvious, the agricultural counties have hitherto failed to show a similar progress as the outcome of their efforts to improve the rural industries. Many causes are contributing in this country to check advancement in rural technical education. The general depression of agriculture, the conservatism and apathy of farmers and landowners, the high cost of carriage of farm produce, and the incompetence of technical instruction committees are among these causes; but it would be out of place to discuss such matters in the columns of a scientific journal, and we are content in admitting that the technical committees in agricultural districts have had a far more difficult task imposed upon them than the committees of urban manufacturing centres have ever been called upon to perform.

In bringing under the notice of the readers of Nature an educational movement which we are firmly persuaded is a movement in the right direction, we have primarily in view the fact—obvious to men of science, but, unfortunately, not so obvious to those more immediately concerned—that agriculture in its widest sense is as much dependent upon scientific research for its advancement as any other industry. The great importance attached to agricultural stations in the United States and Canada, and on the continent, and the splendid results in the way of agronomic research which are being achieved at these stations, amply testify that other countries are alive to their agricultural welfare. All that has been done in this country by those great pioneers, Lawes and Gilbert, has been the result of private munificence.[1]

In view of the fact that the results of scientific research are bound with the progress of time to make themselves more and more felt in all kinds of rural industries, and bearing in mind also the slow rate of development in this direction in our country, we are convinced that the best chance of enabling our agricultural population to appreciate the importance of research and to meet competition is to give the rising generation an opportunity of acquiring some knowledge of sound scientific principles as a part of their early training. If the present generation of farmers and landowners cannot or will not bend to the inevitable, and endeavour to cope with difficulties by scientific method, then, at any rate, let facilities be given to their children for the acquisition of such scientific habits of mind as will enable them, without actually becoming experts in any particular science, to realise exactly how they are situated with respect to their competitors. It is hardly necessary to point out in these columns that in all rational schemes of technical education this principle is recognised as sound. It is remarkable, in view of this acknowledged principle, that so many technical instruction committees should have attempted to begin their work at the wrong end, and should have expended large sums in encouraging sporadic teaching by specialists to adults who, for lack of proper training, are totally unprepared for specialisation in any direction. In most cases a critical analysis of the results obtained under this system shows that unintelligent manual dexterity is the utmost that can be achieved. This, in our view, does not constitute technical education; certainly, so far as agricultural industry is concerned, this kind of instruction is not likely to be of any permanent value.

The agricultural industries may be regarded as furnishing a rallying point round which several distinct branches of science meet. To insure success in such occupations when all the resources of science are being utilised by our competitors, it is becoming more and more imperative that the education of the farmer should, at any rate, be placed on a scientific foundation. We cannot, unfortunately, look at present to the elementary schools for any help in this matter. The children leave too early in life, and such science teaching as they receive (if any) is quite inadequate. The sporadic system encouraged by some County Councils has already been condemned. Still more unfortunate appears to us to be the frittering down policy of administering the technical education grant in the form of doles to districts in proportion to the number of the inhabitants. The few want educating in the thinly populated agricultural districts quite as much, or even more, than the many in the towns. It is more costly to educate the few than the many; therefore the rural districts require more financial aid proportionally than the towns. Under the system referred to, the country districts get less. If an "intelligent foreigner," who came over to inquire into our educational systems since the passing of the Technical Instruction Act, were told that the degree and quality of the education given to a boy or girl had been made dependent on the number of inhabitants per square mile

[1] The fructicultural station established by the Duke of Bedford and Prof. Pickering at Ridgmount also comes under this heading.

in which the child happened to reside, he would be justified in passing on with a smile and a shrug.

Owing to the insufficiency of the educational machinery in country districts, and the disproportionate assistance given to urban centres under the decentralising policy, another evil has arisen which threatens to cripple still more seriously the already languishing rural industries. By the examinational selection of pupils for scholarships the best intellectual products of the country districts are gradually being weeded out, and all the skill and intelligence for which the land is thirsting is being diverted into other channels. This process, if allowed to go on, can only have one result: there will be left such an inferior residue that some future Minister of Education will have to deplore, even more emphatically than did Sir John Gorst in his memorable speech in the House of Commons last June, the barrenness of the outlook with respect to rural education. Still louder will go up the cry of the economist, that while the land is lying barren for want of skilled attention, and the villages are becoming depopulated, the towns are becoming overcrowded to the starvation point of competition.

In order to counteract these evils, it is desirable that the resources of science should be made as available to the inhabitants of the country as to the dwellers in towns. A long acquaintance with the habit of mind of the average British farmer has convinced us that the only chance of salvation in the future is to bring the educational machinery into his neighbourhood. It is useless to tell him that he must send his children to some distant school or college where science teaching forms part of the curriculum. He knows nothing and cares nothing about science. He looks upon learning as a dangerous thing, and associates chemistry with bogus fertilisers. An experiment which leads to no practical issue causes a chuckle, and if a downright failure is the result, he is rather pleased than otherwise. The so-called "agriculture" of the certificated schoolmaster, which was let loose in some counties in the early days of the technical education movement, is very largely responsible for hardening the scepticism of the practical farmer towards science.

Perhaps we are over-sanguine in the belief that the agricultural salvation of our country depends on the scientific education of the coming generation. At any rate the belief has taken practical form, and a school of science has been founded at Bigods, near Dunmow in Essex, by one of the writers (F. E. W.), which it is hoped will set an example throughout the country. No claim is made for any particular educational originality in this venture. The *raison d'être* of the school is that it serves a thinly populated agricultural district where there is no organised science school in existence. There are districts of a similar kind all over the country, and there is a distinct need for such schools in these districts. The Essex County Council has extended some aid towards the Bigods school, and it is to be hoped that other County Councils will follow suit in their own districts. Certainly no better use of the "whisky money" can be made in agricultural districts than in establishing schools of science where the children can receive a sound training, extending over the three or four years between their leaving the elementary school and their entry into life as bread-winners. In some cases it might be possible to develop existing schools in the desired direction; but, on the whole, a fresh start would seem to be the preferable course. The average country grammar school is generally too much hampered by ancient tradition to meet modern requirements; the education in such foundations has not a sufficiently scientific bias, and the particular class of students whom it is our desire to see catered for, do not take kindly to the grammar school curriculum, apart from the question of cost, which is more than the small farmer or proprietor can afford.

With respect to the curriculum at Bigods, we have at present adopted that laid down for schools of science by the Science and Art Department. In most respects this scheme seems adaptable to our requirements, which may be described briefly as an education which, while allowing a certain amount of time for literary subjects, gives also a general scientific training with some manual training. No specialisation will be allowed till the pupils have passed through the elementary stage, and in the advanced course the sciences bearing on agriculture will be given extra prominence. A large mansion has been placed at the disposal of the school as a residence for the principal and for boarders who reside too far off to come to the classes daily. There is plenty of land about the establishment for experiment plots, apiaries and poultry runs, and a farm adjoining the estate is available for field demonstrations. For the advanced classes the services of the County Council Staff Instructors, who are experts in their various departments, will be requisitioned. The school has made a start with some forty pupils, of whom about twenty-three are considered qualified to go through the school of science; while the remainder are in course of training for this curriculum. One especial feature of the scheme is the mixed education of boys and girls together in the same class. This system has been found to work admirably in other schools, both in this country and elsewhere, and it is intended to give it a fair trial in Essex. So far as experimental science is concerned, girls certainly are quite as keen and do just as well as boys if they are properly taught. The only point of difference in the education of the sexes is that the girls sacrifice some portion of the manual training and science in favour of domestic subjects, such as cookery, needlework, and domestic economy. Chemical and physical laboratories, a workshop and well-equipped laundry are, of course, essential parts of the institution.

The educational experiment which has been inaugurated in Essex is one which we venture to think is worthy of success and encouragement. The main difficulty with which we shall have to contend will no doubt be that of persuading the parents to allow their children to remain long enough at the school to complete their education. At any rate, the chance has now been placed in the way of the inhabitants of a district which has hitherto been devoid of institutions for carrying on any systematic scheme of secondary education. The firm belief that such establishments will do more permanent good to the agricultural welfare of this country than any amount of sporadic teaching or evening courses to people already mentally and bodily weary with a long day's work, has prompted the expenditure of money, time and thought, which have been necessary to found this school. Of equal weight has been the conviction that the mental discipline imparted by sound instruction in the principles of such sciences as are taught under the curriculum, is the best of all equipments that can be given to the agriculturist on his entry into active life. In order that would-be benefactors of rural education need not be alarmed, it may be pointed out that large institutions are not essential. At Bigods the laboratories of the school of science are available for about twenty-five pupils. We shall be satisfied if for some years this department of the school can be maintained at this number in the elementary and advanced stages. The great desideratum of the time is the establishment of numerous small but thoroughly efficient secondary and technical schools in appropriate centres, so that all the rural districts may be catered for. The general level of intelligence in the neglected country districts is bound to be raised in the long run by such means—not only by the direct effect of the training, but indirectly by reacting upon the elementary schools and compelling them to increase the efficiency of their teaching.

FRANCES EVELYN WARWICK.
RAPHAEL MELDOLA.

IN THE FORBIDDEN LAND.[1]

AMONGST the many travellers who wander to and fro in the untrodden parts of the world there has lately been a marked development of the journalistic class.

Ever since the days when the *New York Herald* achieved such a grand success with Mr. Stanley, and was instrumental in the discovery not only of the lost Livingstone, but of a vast new world for future enterprise, we have had from time to time new schemes for exploration initiated and supported by leading exponents of popular literature. The difference between the special correspondent and these emissaries of what we may call geographical journalistic enterprise lies chiefly in this; the special correspondent finds the subject-matter of his correspondence ready made for him; he has but to record the sequence of events as they pass before his eyes; over them he has no control, and his success depends largely on the chances and accidents of a campaign or political mission. The journalistic geographer, on the other hand, has to make his own straw before he can produce his bricks; and if startling sensation and thrilling incident are necessary to his success, he must find them for himself. There can be no reasonable objection to this form of enterprise, although the dangers that beset it (both moral and physical) are obvious. Haply the traveller who starts in search of a sensation may discover much that is of real value to science, and may prove to be a sound geographer. But his *métier* should not be confounded with that of the true geographer, the seeker after scientific truths, whose aim is the enrichment of the world's store of exact knowledge, and who will, in the pursuit of his object, avoid rather than court those situations which may peril the safety of his mission and impede his purpose, even if they may add picturesque detail to his narrative.

Mr. H. S. Landor is an adventurous traveller who possesses by heredity the eye of a poet, and a great power of graphic description. His book is interesting all through, but we must not take him too seriously as a great geographer. A journey through the Kumaon district (which constitutes a great part of his book) is but the periodic experience of every official Englishman who is appointed to the administration of that corner of the North-west Provinces, and even a visit to the Mansarawar Lake has not proved to be beyond the powers of several sportsmen lately, who have been more fortunate than Mr. Landor in their relations with the frontier Tibetan authorities. But beyond the Mansarawar Lakes, on the direct route to Lhassa, it has been known for many years that no European has a chance of penetrating far. It is a most jealously guarded route, and those travellers who have studied the subject of traversing Tibet beforehand, and who have lately succeeded in crossing the great northern plateau from west to east, have entered Tibetan territory at points less exposed to the hostile and unrelaxed vigilance of the Tibetan officials. It is true that the region of the Mansarawar Lakes, and, indeed, the whole route to Lhassa has been pretty thoroughly explored and surveyed under conditions of much less difficulty than those experienced by Mr. Landor; but this has been accomplished by trained employés of the Indian Survey department, who, being either residents of Kumaon or educated Tibetans, have been able to identify themselves with the people of the country, and have experienced no particular difficulty in reaching Lhassa, and describing it in comprehensive

FIG. 1.—Escaping in a snowstorm.

[1] By A. Henry Savage Landor. Two vols. Pp. xx + 320, and xvi + 263. (London: W. Heinemann, 1898.)

official reports. Mr. Landor's map differs in no essential particular from that of the Indian Survey, except that he shows an error in longitude. His separation of the Rakas Tal from the Mansarawar Lake by a dividing ridge of some elevation cannot be accepted as a final determination of the real nature of that division, the continuity of which probably depends on the amount of water in the two lakes. Evidence of their connection exists, and in face of the fact that Mr. Landor only partially traversed the dividing ridge, this evidence cannot fairly be set aside.

It speaks much for Mr. Landor's pluck and endurance that he should have succeeded, with two followers only, in penetrating some 200 miles along the high road to Lhassa. Here a forcible conclusion was put to his journey, and his opportunities as a geographical observer came to an end. But what was wanting in opportunity for scientific research was more than balanced by the excitement (unexpected and most unpleasant) of thrilling personal adventure in the hands of the Tibetans; and it is this which gives such strong interest to Mr. Landor's narrative. He crossed the frontier by the Lampiya pass after a preliminary ascent of the Mangshan mountain. After reaching the top of the mountain (22,000 feet) at night, and recording his observations by the light of the moon, he witnessed some extraordinary optical phenomena; and then collapsed under the pressure of sensations such as few travellers have experienced, and from which we may venture to say that none before have ever recovered. High altitudes, no doubt, produce curious effects on the powers of vision. On another similar occasion Mr. Landor observed all the planets and stars oscillating in the sky with something of the motion of a swinging pendulum.

From the Mansarawar Lake eastwards his journey was one of constant difficulty and danger. He evaded the Tibetan outpost by escaping from his camp into the mountains during a severe snowstorm, and wandered amongst the hills for some days before he regained the direct road to Lhassa. So constant were his encounters with bands of dacoits on this much-traversed route, as to lead to a suspicion that these dacoits must gain a precarious livelihood by robbing each other. Their cowardice was, however, phenomenal (and in this trait of Tibetan character all travellers agree), and the simplest demonstration of resistance was enough to put them to flight. Gradually reduced to two followers, with two yaks to carry his small equipment, Mr. Landor still pressed on eastwards until he lost half his baggage in crossing a river. He was driven to a Tibetan encampment for food and for the purchase of ponies, and it was whilst negotiating the latter that he and his two companions were treacherously overpowered and cruelly bound, under the direction of a Tibetan official, who had probably been despatched from Lhassa to prevent his further progress. If Mr. Landor was in search of a sensation, he certainly found it now.

FIG. 2.—Crossing the "divide" between the sources of the Indus and the Brahmaputra.

The rest of his book is a lively description of his sufferings and those of his faithful retainers during their forcible removal from Tibetan territory. One hardly knows which to admire most—the supreme contempt for his captors that Mr. Landor never failed to evince even under the most harrowing circumstances; the pluck and nerve which he showed when face to face with death; or his extraordinary athletic powers, as proved by his clinging to the saddle with his knees when his hands were tied behind him, and a heavy-weight Tibetan was pulling him backwards with a rope tied round his neck; or when, triced up by hands and feet (as illustrated by himself), he was able to liberate one hand and loose the ropes which bound his servant's feet, whilst he still remained suspended by the other.

With Mr. Landor's illustrations, two of which accompany this notice, we have no fault to find. The photographs are excellent, and his own drawings are powerfully descriptive of the impressions which remained in his mind after his adventures were over. The Kumaon hill track where he climbs round the face of the cliff is indeed a perilous path; but anything is possible in a region where the habitations of the natives can cling to the face of a wall in apparent defiance of all laws of gravity, as they do in the illustration which faces p. 159 of vol. ii. But with Mr. Landor's system of spelling we cannot agree. It is *not* the "geographical" system, and it is at first a little difficult to recognise well-known Hindustani words in the guise in which Mr. Landor clothes them. The words "Acha giao" (achcha jao) would not in the mouth of a Pahari gypsy mean "Go well" so much as "All right, clear out."

And there is one other subject which we think requires further investigation. The habits and manners of Tibetans have often been described, sometimes by themselves, sometimes by scientific observers. But Tibetans have never so far been classed amongst cannibals. The revolting details which Mr. Landor gives of the practices of the Lamas in connection with the last rites of a dead Tibetan are too horrible to be admitted without question. It should be remembered that Mr. Landor deals with a section of the Tibetan community which is directly connected with the great religious centres at Lhassa. It happens that it is about these centres that we possess the fullest information. No Lama in the neighbourhood of Darjiling would admit for an instant that such practices were common; nor will the reports of educated native travellers to Lhassa support the accusation. Mr. Landor carries his search for sensation just a little too far when he accepts in all good faith accusations such as this without an appeal to the best authorities.

With reference to the appendix to Mr. Landor's book, and the report of Mr. Larkin, the Deputy Commissioner of Almorah, the following extract from the *Pioneer Mail* of October 14 will be interesting.

"We have the best authority for stating, as we did the other day, that Mr. Landor was told that this report was confidential, that no copy was given him, and that he was not authorised to publish any Government report." The certified copies of depositions made in Mr. Larkin's Court should not be mistaken for Mr. Larkin's report.

T. H. H.

BODE'S LAW AND WITT'S PLANET DQ.

IN comparing the distances of the planets from the sun, it was early thought that there might be some law which would connect these distances together and allow us to calculate them correctly or even approximately. Kepler, as long ago as the beginning of the seventeenth century, thought that he had discovered such a law; but as he could not account for the anomalous space between the orbits of Jupiter and Mars, he abandoned the idea "of reconciling the *actual* state of the planetary system with any theory he could form respecting it, and hazarded the assertion that a planet really existed between the orbits of Mars and Jupiter, and that its smallness alone prevented it from being visible to astronomers." In the year 1772 Prof. Bode announced a law which gave a curious approximate relation between these distances, although it seems certain that Titius of Wittenberg discovered and formulated it some years previously, pointing out "the existence of a remarkable symmetry in the disposition of the bodies constituting the solar system." This law was very simple, and amounted to this: If to each of the planets, beginning with the one nearest the sun, the number 4 be given, and to the second, third, fourth, &c., the numbers 3, 6, 12, &c., respectively, be added, then the resulting numbers, divided by ten, approximately give the values for the mean distances of each planet from the sun in terms of the radius of the earth's orbit.

The first six numbers calculated by this law gave with fair accuracy the relative distances of the planets; but there was one exception, namely the number 2·8, which represented the distance of a planet when there was nobody known: this exception was the same that puzzled Kepler in the formation of his law. Prof. Bode supposed, however, a hypothetical planet to fill up this gap, which probably was absent simply because it had not then been discovered. We may mention that at that time Uranus and Neptune had not been found, so that the discrepancy with regard to the latter planet, in which this law utterly breaks down, could not then have been noticed. As this one feature in the law could not otherwise be explained, namely the number which accounted for the distance of a planet between Mars and Jupiter, a planet which had never been observed, it was decided to make a thorough search and try to pick up this missing member. The discovery of Uranus in 1781, and its distance agreeing with the value as given by Bode's law, set many astronomers thinking, with the result that it was decided to make a systematic search in the heavens for this unknown planet. Although all those who undertook this search worked diligently to pick up this supposed body, it was left for Piazzi, the Sicilian astronomer at the observatory of the University of Palermo, to make the discovery of the first (Ceres) of those now numerous small bodies known as planetoids, asteroids, or minor planets, which make their journey round the sun between Mars and Jupiter.

Piazzi, it may be remarked, was at the time constructing a star catalogue, and discovered this small body in his usual course of work, thinking at first it was a new kind of comet.

This was the first of a series of discoveries which now followed one another, and, up to the beginning of this year, no less than 425 of these planetoids have been discovered. The question then was asked, Did Bode's law still hold good? Were these small bodies, which vary in size from 100 to 10 miles in diameter, remnants of one large planet which originally revolved between Jupiter and Mars at a distance approximately the same as that represented by Bode's number 2·8?

Taking the distance of the mean minor planet, namely 2·650, and comparing it with the computed value from Bode's law, namely 2·8, the agreement was found to be sufficiently satisfactory for such an approximate law. In the case of Saturn, the difference between the mean distance and that given by Bode's law is nearly three times that for the minor planet above mentioned, so that the law may be said to approximately hold good.

In the case of Neptune, which was discovered in 1846, the value of the mean distance, according to Bode's law, is far from the true one, so that the law in this case may be said to completely break down.

Quite recently another planet, not a member of the minor planet family, as far as we know, but one revolving by itself, in an orbit between Mars and the Earth, has been added to the members of the solar system. Does Bode's law account for this? Before answering this question, let us, first of all, confine our attention for a moment to the manner in which this body was discovered, and what we as yet know about it.

In the early days of minor planet discovery, the task of finding one of these heavenly wanderers was by no means a light one; for the watcher had not only to be provided with an excellent star map of the region of the sky he was studying at the time (he nearly always constructed one himself), but to make measurements of each of the bright points in his field of view, night after night, to see if he could detect any relative motion between them. Considering the number of stars in the

region under investigation, and the improbability of there being a minor planet in that region at that time, it can be quite well understood that such discoveries were the result of an immense amount of labour. By the use of the photographic method, all these difficulties are at once swept on one side; for, since the presence of one of these bodies can only be detected by its own motion relative to the stars around it, the photographic plate can at once indicate this. Further, by using a fairly wide angle lens, a far greater portion of the sky can be examined at one time than was previously the case, and therefore the chance of finding these bodies is considerably increased.

We have only to expose a photographic plate in an equatorially mounted telescope driven by clockwork at sidereal rate, then all stars will appear as circular discs, and any minor planet, which, of course, has its own proper motion, will be represented by a small trail, the length of this depending on the duration of the exposure and the amount of movement of the minor planet during that interval.

plate searched for are by no means easily seen. The plates, further, must always be carefully washed for some hours, in order to get rid of all trace of the hyposulphate of soda. It is an exceedingly easy matter to quickly dry photographic plates; but most methods, even that of the use of alcohol, are inclined to create disturbances in the film, such as unequal contraction, which render it unfit for accurate measurements afterwards.

Herr Witt therefore waited until the following day before the negative was examined. Not only did he find on it the record of the long-lost minor planet he was seeking after, but another one, Althaea (119), which had been previously discovered. With the help of a lens a further trail was noticed, but on account of its unusual length, which was an indication of a quick moving body, he thought at first it must be a comet. To verify this conclusion, the following evening he turned the 12-inch refractor towards the same region, and found in that position a stellar- not cometary-like body of magnitude 10 to 11. Without any further delay the dis-

FIG. 1.—Showing path of new planet in sky between August 14 and December 31, 1898.

At the present day numbers of workers are exposing plates on clear nights to detect both new and old members of this family, and it was during such a search that Herr Witt, of the Urania Observatory in Berlin, made the important discovery of this new planet.

Since the year 1889 a certain minor planet named Eunike (185) has never been observed, and it was with the intention of photographing this object that Herr Witt turned his telescope, on the night of August 13, towards the region of β Aquarii, previous calculation having told him that the planet should be in or near that region. After a two hours' exposure the plate was developed and washed, and left to dry until the next day, when it was carefully examined. It may be asked, why the plate, after development, was not immediately examined? Any one who is familiar with such work will know that not only is the film very soft, and therefore easily liable to be damaged, but that the trails on the

covery was at once communicated to the "Centralstelle" for astronomical telegrams, and by this means the news was immediately sent to a great number of observatories.

Curiously enough, on the same evening (August 13) that Herr Witt was fortunate enough to photograph the trail of this planet, Herr Charlois, at the Nice Observatory, was photographing the same region (probably with the same intention as Herr Witt). He also secured a record of the presence of this new body. Prof. Perrottin, the director of the observatory, did not, however, make the discovery known until after Herr Witt's announcement; nevertheless, although the latter is entitled to declare himself the real discoverer, both names should be handed down to posterity, as is the case with the discovery of Neptune by Leverrier and Adams.

It was not long, however, before numerous accurate observations of this new body were made, and they extended over a period of days (seventeen in number)

sufficient to allow that well-known indefatigable minor planet-orbit calculator, Herr H. Berberich, to compute its orbit. The accompanying chart (Fig. 1) shows the path of the planet in the sky from August 14 to December 31. The Roman figures in the chart from VIII to I correspond to the dates August 14, September 1, October 1, November 1, 15, December 1, 15, 31, of the present year.

Now comes the astonishing result of Herr Berberich's computation. The planet was not one of those small bodies which revolve round the sun between Mars and Jupiter, but was an entirely new body, its path lying for the main part within that of Mars.

Here are the elements of the planet's orbit as given by the calculations. It must be mentioned, however, that these elements cannot be considered as final, since more observations, extending over a much longer period, are required to ultimately establish the true elements. These elements, however, will not deviate very much from those given below.

Epoch 1898, *August* 31·5, *Berlin Mean Time.*

	°	′	″	
Mean anomaly	220	14	3·7	
Perihelion distance from ascending node ...	178	28	26·2	1898·0
Longitude of ascending node	303	48	53·0	1898·0
Inclination of orbit to that of the earth ...	11	6	57·1	1898·0
Eccentricity	13	13	3·8	

Mean daily movement, 2010″·131
Period of revolution round the sun, 645 days.

Taking the mean distance of the earth from the sun as unity, the new planet at perihelion approaches the sun to within 1·12 of these units, and when furthest away is distant 1·79 of these units. These values in the case of Mars are 1·38 and 1·67 respectively. We thus see that we can now no longer look upon Mars as our nearest neighbour (excepting, of course, our moon), for the mean distance of Mars from the sun amounts to 1·52, while that of the new planet is 1·46.

The accompanying diagram (Fig. 2) shows the relation of the new planet's orbit relative to that of Mars.

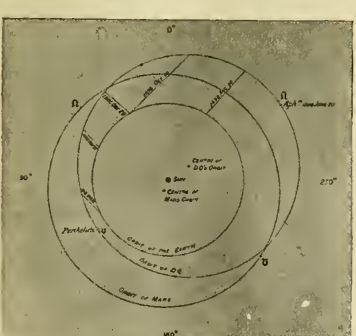

FIG. 2.—Comparison of orbits of Mars and the new planet D Q.

Assuming that Berberich's elements are correct, it is interesting to inquire into some of the relations which this orbit presents. Mr. Crommelin, to whom we are indebted for the above diagram, has considered such relations in his article in *The Observatory* (October, p. 372). A synodic period being two successive conjunctions with the sun as seen from the earth, this in the case of the new planet is 2·30692 years. We thus see that three synodic periods equal nearly seven years, so that after this period oppositions are repeated in nearly the same regions of the orbit. A closer approximation would be obtained if thirteen synodic periods, which extend over 29·99 years, were considered. As regards the time when the planet comes into opposition—a point of great importance, especially in the case of this planet—Mr. Crommelin tells us that, unfortunately, "an opposition under the most favourable circumstances took place in January 1894," and that we shall have to wait now until January 1924 until another equally favourable one occurs. In the years 1900 and 1917, only moderately favourable oppositions will occur, the planet in November of the former year then being of magnitude 8 or 9.

The close approach of this planet to the earth at times of favourable opposition will give us excellent opportunities of determining, more accurately than was possible before, the parallax of the sun—or, in other words, the distance of the sun from the earth.

The importance of a correct value of this quantity is very great, when it is considered that all measurements of distance in our solar system are based on it. Just as the foot is taken as a unit in measuring the side of a room, or a mile in measuring a strip of country, so astronomers adopt the mean distance of the earth from the sun as the unit in measuring the distance of Jupiter or Mars. A more accurate value of the standard of measurement for the solar system is, therefore, of the highest importance.

Since the new planet when nearest to and furthest from us will vary from the sixth to the twelfth magnitude, several useful photometric problems may be attacked. Thus, as Prof. Pickering suggests, the approximate diameter may be determined by comparing it with those of the brighter minor planets and satellites, on the assumption that the reflecting power is the same.

Again, the well-known law that light varies inversely as the square of the distance might be tested, as the planet's distance from the earth varies very considerably. At the same time, it could be determined whether there exists in the solar system any medium capable of absorbing light.

Let us now consider whether the law of Bode holds good for the presence of this new planet.

We give below a table showing a comparison between the true mean distances and those calculated by Bode's law.

Planet.	Distance.	Bode.	Diff.	Syn. period. Days.
Mercury ...	0·387 ...	0·4 ...	−0·013 ...	116
Venus ...	0·723 ...	0·7 ...	+0·023 ...	584
Earth ...	1·000 ...	1·0 ...	0·000 ...	—
Witt DQ ...	1·461 ...	? ...	— ...	644·7
Mars ...	1·523 ...	1·6 ...	−0·077 ...	780
Mean asteroid ...	2·650 ...	2·8 ...	−0·150 ...	Various
Jupiter ..	5·202 ...	5·2 ...	+0·002 ...	399
Saturn ...	9·539 ...	10·0 ...	−0·461 ...	378
Uranus ...	19·183 ...	19·6 ...	−0·417 ...	370
Neptune ...	30·054 ...	38·8 ...	−8·746 ! ...	367·5

In the above table the column headed "Bode" gives the distance according to the law of Bode, while the following column, that headed "Diff.," represents the difference between the true mean distance, as given in the second column, and that calculated after Bode's law.

A glance at this will show that the distance of the new planet does not fall into line at all, but, like Neptune, is an exception to the law.

Indeed, for the new planet, Bode's law does not even suggest a number, as there is no break between the distance accorded to our Earth and that of Mars. If we assume the law of Bode as mainly correct, then we must look upon the new planet as one of the minor planets gone somewhat astray.

There is, however, one outlet which believers in this law can take advantage of, namely, that perhaps the new body was originally part of the planet which, when broken up, gave rise to the group of minor planets. As opinion is still divided as to the true origin of asteroids, namely, whether they are the result of a large series of explosions of an original planet which revolved between Mars and Jupiter; whether they are the condensation of matter which originally was distributed in rings like Saturn, but which was disturbed by the action of Jupiter; or, lastly, whether they are the result of tidal action on the tenuous primitive masses, the presence of the new planet in this exceptional orbit might be accounted for on any of these hypotheses. Perhaps, for all we know, this planet may be one of several similar bodies which were so thrown off or perturbated from the original mass, that they were able to get into more favourable positions for being disturbed by the attraction of Mars when nearest them, and that their orbits were changed.

Mr. Rees, in a lecture before the New York Academy in 1897, suggested that "the very rapid augmentation in the number of minor planets indicates that there may be thousands or even millions in the zone: with more powerful telescopes and more sensitive plates we may hope to find many of these thousands. And perhaps the same agencies will discover asteroids between the orbits of all the planets." There is, however, no doubt that the orbits of some of the minor planets are not very dissimilar from those of Mars and Jupiter, and must be subjected at times to large disturbing forces by both these planets. That one, or even several, of these bodies may have been violently disturbed by Mars when in a very favourable position, and thus made to revolve in orbits more eccentric and inside that of Mars, does not seem at all improbable.

Jupiter also would be responsible for a great disturbing force, and it is as likely as not that beyond his orbit many of these small bodies pursue their paths; these, however, would probably be invisible to us on account of the greater distance. In fact, it seems more natural and in harmony with the solar system in general to consider this newly-discovered small planet as an unusually situated member of the minor planet group, than as a single condensed body which has from the beginning of its career been up till now an unseen major planet.

If future research on the movement of this new body should indicate the probability that we are dealing with a member of the minor planet group that has suffered considerable perturbations, then the law of Bode will, with the ususal exception (Neptune), still afford us the simple approximate means of quickly calculating the distances of the members of the solar system.

WILLIAM J. S. LOCKYER.

NOTES.

WE regret to see the announcement of the death of Mr. Latimer Clark, F.R.S., the well-known electrician, at the age of seventy-six.

PROF. JAMES A. CRAIG, of the University of Michigan, spent his summer vacation in London at work in the British Museum, on the astrological-astronomical tablets of the Kujundjik (Nineveh) collection known as the Illumination of Bêl. This is the most important series of unedited texts in the British Museum, and by far the most important in many respects to be found in any of the collections extant. Prof. Craig has worked upon it during the last three summer vacations, and has now completed all the texts of the series, which number about 130 tablets. His manuscript is already in the press with Die Hinrichssche Buchandlung, Leipzig, and will appear shortly in the "Assyriologische Bibliothek," in which the author has already published two volumes.

THE Paris correspondent of the *Chemist and Druggist* states that Dr. Calmette, Directeur of the Pasteur Institute at Lille, has endowed that body with a sum of 250,000 francs (10,000*l*.), representing the profits realised by the distilleries at Seclin by one of his inventions.

Natural Science, the impending decease of which was announced in the October number, has received a new lease of life. An editor has been found willing to take upon himself the burden of responsibility, so the journal will appear as heretofore during 1899, and, it is hoped, for many years to come.

THE Committee on endowment of the Franklin Institute, Philadelphia, is making an appeal for subscriptions to the endowment fund. It is of the utmost importance for the future prosperity and progress of the Institute, that a substantial addition to its annual revenues be acquired, not only to provide income sufficient to carry on its present work, but also to enable it to extend this in other directions.

PROF. ISRAEL C. RUSSELL, of the department of geology of the University of Michigan, has recently conducted a geological survey for the United States Government over the northern portion of the Cascade Mountains. The greater part of the work was in Washington State, and extended from the Northern Pacific railroad to the Canadian boundary, crossing the mountains several times. Among the places of interest visited was Glacial Peak, the height of which was verified.

AT the close of the last, and the beginning of the present week, the weather over these islands was of a very unsettled character. On Saturday, October 29, a cyclonic disturbance appeared off the south of Ireland, and subsequently passed to the Shetlands, causing gales, especially over the western and northern parts of the country, and rough weather in the Channel and Bay of Biscay, with very heavy rainfall generally, amounting in forty-eight hours to 1·26 inches at Greenwich and 2·48 inches at Pembroke, while thunder and lightning were observed at several places. At Camberwell Green (south-east London) a terrific squall, resembling a small tornado in its character, occurred at about 9h. 30m. on Saturday evening, overturning vehicles, uprooting trees, and causing much damage to buildings. The violence of the storm, the track of which was apparently from about E.S.E. to W.N.W., fortunately lasted only a few minutes, and was confined to a very small area, other places in the immediate locality experiencing nothing beyond strong wind accompanied by very heavy rainfall.

THE ordinary general meeting of the members of the Institution of Mechanical Engineers was held on October 26 and 27, Mr. Samuel W. Johnson, the president, being in the chair. The president announced that Sir W. H. White, Chief Constructor of the Royal Navy, had been nominated as his successor, Mr. T. Hurry Riches as a vice-president, and Sir William Arrol, M.P., Sir Benjamin Baker, Mr. Henry Chapman, Mr. W. J. Pirrie, and Sir T. Richardson, M.P., as members of the Council. In a paper on "Electric installations for lighting and power on the Midland Railway, with notes on power absorbed by shafting and belting," Mr. W. E. Langdon showed that an extensive loss of power takes place in shafting and belting, but this may be reduced by driving each tool or machine direct from an electric motor. With large tools or machines absorbing over one horse-power, there seems to be no question of the advantage derived from driving them direct by electricity. Mr. W. M. Smith described some recent practical experience with express locomotive engines. The train resistance was found to be considerably increased by side winds. On one trip it was found that the side wind increased the mean train resistance by about 3·558 lbs. per ton of load. The

dynamometer apparatus used in the experiments measured and recorded (1) the pull or push exerted by the engine on the train; (2) the distance run; (3) the speed; (4) the places of starts, stops, and stations; and (5) the time when starts and stops were made, and when stations were passed. The horse-power shown by the indicator diagrams differed from that recorded by the dynamometer, which was in a separate car. Usually, however, the ratio between the two horse-powers did not vary much. On an average the dynamometer horse-power was equal to approximately 64 per cent. of the indicated horse-power. Thus about 36 per cent. of the driving power was absorbed by the engine and tender.

Mr. N. R. Harrington and Dr. Reid Hunt have arrived in New York from the Nile valley, where they have been several months collecting *Polypterus* and other interesting and valuable cytological material. We learn from *Science* that the chief object of the expedition was to procure the life-history of *Polypterus* and its bearings upon the problem of the relation of the Crossopterygian fishes to the Amphibia. In the last few years the former theory that Amphibia sprang from Dipnoan fishes has gradually given way to the present view that *Dipnoi* are to be regarded as parallel to Amphibia from a common Crossopterygian origin. Several very successful expeditions have been sent out to procure material for the embryology of Dipnoans, notably that of Prof. Richard Semon from Jena, and that of Mr. Graham Kerr from the University of Cambridge. The former secured the complete life-history of *Ceratodus*, and the latter brought back the embryology and complete life-history of *Lepidosiren*, a South American form. But before the recent expedition nothing had been done upon the development of *Polypterus*, because of the exceptional difficulties which stood in the way of procuring material. Messrs. Harrington and Reid found that the fish did not occur in Lake Menzaleh during the low Nile period, but they came across several *Polypterus* near Ras-el-Ghelig. The best *Polypterus* fishing ground, not closed on account of the Sudan campaign, was at Mansourah, forty miles from the sea; and the party settled there for the summer.

The attention of botanists has of late years been turned to the biology of ferns, but there still remain a great many facts to be explained, and questions to be solved. Dr. Aurelio de Gasparis, in a paper to be published in the *Atti* of the Naples Academy, has brought to light a large number of new facts relating to ferns. Some of these relate to certain forms of dissemination not previously observed, others to the trophilegic action of the fronds, in connection with which certain arrangements have been observed, destined to facilitate the passage of water to the roots. The author has also discovered two new cases of myrmecophily, as well as a number of cases of acarophily among ferns, many of them very evident and easy of observation.

An interesting addition to the list of myrmecophilous plants furnished with so-called "extra-nuptial" nectaries is given by Prof. Federico Delpino in the *Rendiconto* of the Naples Academy, iv. 7. In the Botanical Gardens at Naples about seven or eight plants have recently been observed to possess these glands, which differ from the ordinary melliferous glands in not being associated with the floral organs and being provided for the purpose of attracting ants instead of for promoting fertilisation. The newly-observed cases occur in *Cardamine cheledonia*, L., *Lilium croceum*, L., *Dyckia regalis* and *D. remotiflora*, a species of *Aechmea*, *Iris foetidissima*, L., and *Vicia serratifolia*, Koch. The families of *Cruciferae* and *Bromeliaceae* are thus added to the fifty-eight families previously known to contain species furnished with the glands in question.

In a paper, published in the *Sitzungsberichte* of the Berlin Academy of Sciences, Dr. F. Johow states his belief that the number of flowers pollinated by the agency of birds is much smaller than is often stated. Humming-birds, in particular, since they feed entirely on insects, and not on nectar, play but a small part in the carriage of pollen. He describes, however, an unquestionably ornithophilous flower in a Chilian Bromeliad, *Paya chilensis*. The "nectar" in this flower is exceedingly abundant, but is not attractive to insects, being very watery, and containing but little sugar. It is, however, eagerly drunk by humming-birds, but more especially by the "Chilian starling," *Curaeus aterrimuus*; and these birds get their heads plentifully besprinkled with the pollen, which they then carry to other flowers.

Prof. Ramsay has an article on the kinetic theory of gases and some of its consequences in the November *Contemporary*. He explains Dr. Johnstone Stoney's application of the kinetic theory to the atmospheres of planets and satellites, and then considers the recent discoveries of gaseous constituents of our own atmosphere, with special reference to the new element "neon." The facts dealt with are summed up as follows: "We have seen, then, that the discovery by Lord Rayleigh of a discrepancy in the density of atmospheric nitrogen has resulted in the discovery of a new constituent of air, argon; its discovery has led to that of a constituent of the solar atmosphere, helium; speculations on the ultimate nature and motion of the particles of which it is believed that gases consist has provoked the consideration of the conditions necessary in order that planets and satellites may retain an atmosphere, and of the nature of that atmosphere; the necessary existence of an undiscovered element was foreseen, owing to the usual regularity in the distribution of the atomic weights of elements not being attained in the case of helium and argon; and the source of neon was therefore indicated. This source, atmospheric air, was investigated, and the missing element was discovered."

The expressions for the work done in magnetising a body have been given by Mascart and Joubert and Prof. J. J. Thomson, by Prof. Ewing, and by Prof. Ascoli respectively in three different forms, all of which lead to the same results when applied to closed cycles, but differ in the values they give for the work done in an open transformation. An interesting examination of these formulæ is given by Signor Guido Grassi in the *Rendiconto* of the Naples Academy, vi. 7. The author finds that Ewing's formula $(1/4\pi)\int H dB$ represents the general expression of the total work of magnetisation; that $\int H dI$ represents the difference between the total work of magnetisation and the work which would have to be expended in order to create the magnetic field if the latter did not contain any bodies of magnetic permeability different to that of air; and that the expression $\int I dH$ does not represent the work of magnetisation except in the case of a closed cycle.

Prof. B. O. Peirce and Mr. R. W. Willson have for several years been engaged in an attempt to measure, by the aid of the "Wall method," the thermal conductivities of certain relatively poor conductors, and the variations of these conductivities with the temperature. The methods they have adopted, and the results of a number of observations, are now published in the *Proceedings* of the American Academy of Arts and Sciences (vol. xxxiv. No. 1, August 1898). In the present paper the results are given of determinations of conductivities of about twenty specimens of marble of different kinds, when the faces of slabs of the material are kept at temperatures of about 18° C., and 45° C., compared with the conductivity of a special brand of glass which appeared to be practically constant within the limits of the measurements. It appears that the conductivity of a specimen of marble at ordinary mean temperatures may depend, to the amount of several per cent., as

Messrs. Hershell and Lebour have shown, upon the amount of moisture which the specimen holds. An accuracy of only one per cent. is therefore claimed for the determinations. The absolute conductivities of the marbles, calculated on the assumption that the conductivity of the standard glass was 0·00277, are between 0·00501 and 0·00761. Special attention is drawn to two groups of fine-grained marbles, which have conductivities of about 0·0068 and 0·0076 respectively, at about 30° C.

THE principal facts referring to the origin of the metamorphosis of insects are summarised by Mr. J. W. Tutt in the volume of *Transactions* just issued by the South-Eastern Union of Scientific Societies (Taylor and Francis). Metamorphosis, he concludes, appears to be an adaptive habit which certain insects have adopted, in their struggle for existence against those enemies by which they are everywhere surrounded, and against those animals that compete against them for food. The habit of flying, by which they are able to escape from numberless enemies that have not this power, was probably one of the first factors in their development that led to their ultimate success. The additional ability to store up food in the early active (larval) stages of their existence so as to allow them to adopt a hiding habit and quiescent external form at the most critical period of life, must, however, have been the proximate cause of that success which has culminated in their being numerically the most successful types of terrestrial life in existence, the number of species being almost incredible.

WRITING with reference to the account of the resuscitation of a toad taken from a snake, which appeared in NATURE of August 11 (p. 344), a correspondent in the Purneah district, India, informs us that similar occurrences are common in parts of India. He remarks:—"Almost any snake can be made to disgorge what he has just eaten if worried a bit, and on numberless occasions I have seen this done with grass snakes, and seen a toad or frog, generally the latter, hop away rejoicing.... Snakes when angry or alarmed apparently have the power of throwing up their food, and only the other day I caught a 'dhamin,' a harmless but very savage snake—a small one, about 40 inches long—and put him in a box with a glass lid. The next morning I found two half-digested rats which the snake had thrown up. The same thing happened once with a black cobra, whose meal had also consisted of two rats with the addition of a sparrow."

A VOLUME of *Transactions and Proceedings* (vol. xxx., 1897) of the New Zealand Institute, edited and published under the authority of the Board of Governors of the Institute by Sir James Hector, K.C.M.G., F.R.S., has been received. Several of the papers in it have already been referred to; and the limitations of available space prevent us from referring to more of the present volume than a presidential address by Mr. W. T. L. Travers on material and scientific progress in New Zealand during the Victorian Era. Sir James Hector's work in New Zealand justly entitles him to distinction among the explorers and discoverers who have advanced the knowledge of the physical characteristics of the globe during the past sixty years. He commenced his duties as geologist to the Provincial Government of Otago in 1861, and under his direction very valuable investigations were made. Mr. Travers points out, however, that geological work in the field practically ceased in 1893, since which date Sir James Hector has not been provided with the necessary staff for pursuing it. Why this is the case is not clear, but the interruption in the work of one of the most important scientific departments of the Colony is much to be regretted.

REFERRING to the biological interests of the islands of New Zealand, Mr. Travers remarks, in the address referred to, that though the reptilian life found is very limited in extent, it contains two forms of the most remarkable character—namely, the *Tuatara* lizard and a frog known as *Leiopelma hochstetteri*, found chiefly in the Coromandel district. The lizard is only now found in some of the outlying islands, where its continued existence is threatened by the introduction of the pig and the cat. The affinities and structure of this reptile have been the subject of many memoirs, both by New Zealand and foreign naturalists, who have shown that it is evidently connected with some of the most ancient fossil forms. The frog is remarkable chiefly as occurring in an oceanic island. It is satisfactory to know that the fauna and flora of New Zealand have been, and are, studied by many collectors and investigators, the results of whose work have been embodied either in separate volumes or manuals published by the Government under the editorship of Sir James Hector, or in the shape of memoirs in the *Transactions* of the New Zealand Institute, such as those in the volume lately issued.

THE age of Niagara Falls, as indicated by the erosion at the mouth of the gorge, was the subject of a paper by Prof. G. Frederick Wright, read at the recent Boston meeting of the American Association. The late Dr. James Hall early noted the significant fact that "the outlet of the chasm below Niagara Falls is scarcely wider than elsewhere along its course." This is important evidence of the late date of its origin, and it has been used in support of the short estimates which have been made concerning the length of time separating us from the Glacial period. A close examination made by Prof. Wright this summer greatly strengthens the force of the argument, since he found that the disintegrating forces tending to enlarge the outlet and give it a V-shape are more rapid than has been supposed. As the result of his investigations, he concludes that a conservative estimate of the rate of disintegration for the 70 feet of Niagara shales supporting the Niagara limestone would be one inch a year, with a probable rate of two inches a year. But at the lowest estimate no more than 12,000 years would be required for the enlargement of the upper part of the mouth of the gorge 1000 feet on each side, which is very largely in excess of the actual amount of enlargement. Some of the recent estimates, therefore, which would make the gorge from 30,000 to 40,000 years old, are regarded as extravagant. According to Prof. Wright, the age of the gorge cannot be much more than 10,000 years, and is probably considerably less.

DR. AD. STRUCK, of Salonica, contributes an interesting paper on the Macedonian Plain to the issue of *Die Natur* for October 9. Some details of the mean temperature and rainfall are given, and a short account of the chief products of the region.

THE *Bollettino* of the Italian Geographical Society for October contains a paper, by M. Baratta, on the geographical distribution of earthquakes in Umbria. All the authentic records in existence are summarised and discussed, and a map showing the chief regions of seismic disturbance is appended.

WE have received a copy of the double number of *Spelunca*, the organ of the French *Société de Spéléologie*, for the first half of the current year. This journal is now in the fourth year of its existence, and it continues to publish valuable papers on subjects connected with caves and other subterranean structures. The present number contains some notes of interest on the protection of sources of potable water, indicative of increased attention to this matter in France.

A PAPER, by Prof. Dr. J. Walther, on historical and geological aspects of the problem of the course of the Oxus, appears in *Petermann's Mittheilungen*. Dr. Walther shows that the Oxus has always flowed into the Sea of Aral, and that the belief that its waters reached the Caspian arose from ignorance of the

existence of the Sea of Aral, and from the credit given to the fanciful reports of the English merchant Jenkinson, who travelled from Astrakhan to Bukhara in 1558.

A COPY of the general report of the work carried on by the Geological Survey of India for the period from January 1, 1897, to April 1, 1898, has been received. The headquarter notes, forming the first part, announce amongst other things the removal of the offices of the department to a new building which affords improved accommodation, but the Director pleads for transference of headquarters to a hill station. The second half of the report gives short accounts of nine separate surveying expeditions, including one on the north-west frontier by Mr. H. H. Hayden, who was permitted to accompany the Tirah Expeditionary Force.

THE September number of the *National Geographic Magazine* contains papers on the growth of the United States, by W. J. McGee; on the Bitter Root Forest Reserve, by Richard U. Goode; on Atlantic Estuarine tides, by M. S. W. Jefferson; and on the forest conditions of the State of Washington, by Henry Gannett. Mr. McGee's paper traces the growth of the States in area, population, wealth, railway-mileage, and carrying trade since 1790, and shows that the history of the growth of the United States is one of unequalled progress in all these elements, but, above all, in "development of a national character in which individual enterprise and capacity are the most conspicuous traits."

FOUR new parts of the second edition, revised, of "An Illustrated Manual of British Birds," by Mr. Howard Saunders, have been received from Messrs. Gurney and Jackson. Twelve parts of the work have now been published, and eight more have yet to appear to complete the work.

A RICHLY illustrated book for nature lovers is "An Elementary Botany" by Prof. George F. Atkinson, of Cornell University, announced for early publication by Messrs. Henry Holt and Co. Among the more than five hundred pictures are many full-page landscapes in half-tone.

MESSRS. ARCHIBALD CONSTABLE AND CO. will publish, early in November, "The Life of the late Sir Charles Tilston Bright, C.E., M.P.," wherein is included the story of the first Atlantic cable, the first telegraph to India and the Colonies, and the early land telegraphs of the United Kingdom. This work is written by Mr. E. B. Bright and Mr. Charles Bright, brother and son respectively of the subject of the memoir. The book, which contains many full-page and text illustrations, as well as photogravure plates, maps, charts, &c., will be published in two volumes.

UNDER the title of *Sell's Commercial Intelligence* a weekly newspaper has been started with the object of publishing authentic commercial intelligence, and developing British trade. The periodical will do a useful service to British industry if it will show our manufacturers how technical education and scientific research abroad have enabled other nations to beat us in the markets of the world. The following note on a decrease in the exports of chemicals is interesting in this connection :—"The American Consul at Liverpool points out that the exportation of chemicals from the Liverpool districts to the United States, has fallen from about nine million dollars in 1891 to a little under four million dollars in 1897, and at the present rate the exportations for 1898 will only amount to about a quarter of a million dollars. He comments on the application of electrolysis to chemical manufactures, and points out that where electricity can be produced by water-power, as at Niagara and many other places in the United States, the new process will have a better chance of success than in England." We are glad to see that a series of equivalents of British and metric measures is commenced in the new journal.

THE additions to the Zoological Society's Gardens during the past week include a Drill (*Cynocephalus leucophaeus*) from West Africa, presented by Mr. Alfred J. Dempster; two Wild Canaries (*Serinus canarius*) from the Canary Islands, presented by Mr. W. H. S. Quintin; two Tarantula Spiders (*Mygale*, sp. inc.) from the West Indies, presented by Mr. H. R. Taylor; a Common Hamster (*Cricetus frumentarius*), European; a Matamata Terrapin (*Chelys fimbriata*) from Brazil, deposited; a Blue Jay (*Cyanocitta cristata*) from North America, a Naked-throated Bell-bird (*Chasmorhynchus nudicollis*) from Brazil, a Common Boa (*Boa constrictor*) from South America, purchased; two Cockateels (*Calopsitta novae-hollandiae*), a Graceful Ground Dove (*Geopelia cuneata*), a Spotted Turtle Dove (*Turtur suratensis*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

NEW ALGOL VARIABLE.—A Kiel Circular (No. 14) tells us that Mr. Sawyer has discovered a new variable of the Algol type $+ 12^\circ$ 3557. Its period is very short, amounting to 0·89 days; the change in magnitude during this interval being 7·0 to 7·5. A minimum occurred on October 3·54 last, Greenwich mean time.

COMET BROOKS.—Kiel Circulars Nos. 13 and 14 give the elements of this comet as computed by Ristenpart and Möller on the one hand, and Hussey on the other. Those of the latter were computed from observations made on October 21, 23 and 25, and are as follows :—

T = 1898 November 23·14 Greenwich M.T.

$$\left.\begin{aligned} \omega &= 123^\circ\ 22' \\ \Omega &= 96\ \ 10 \\ i &= 140\ \ 19 \end{aligned}\right\} 1898{\cdot}0$$
$$q = 0{\cdot}7564$$

The ephemeris which accompanies these elements is only computed up to November 8, so we give below the position of the comet on that day for Greenwich midnight.

R.A. = 17h. 44m. 52s. Dec. = $+ 12^\circ\ 41'$.

The comet is rapidly decreasing in declination, and will be found in the region south of λ and δ Herculis, moving in the direction but slightly to the west of α Ophiuchi.

The Circular further states that the orbit of this new comet is similar to that of Comet 1881 IV. This latter was discovered by Schaeberle, and was visible to the naked eye for more than two weeks in August, its tail being over 10° long on August 21. Telescopically it was visible for a period of fourteen weeks.

THE ORBIT OF CASTOR.—Prof. Doberck, of the Hong Kong Observatory, has recently been investigating the elements of the orbit of Castor, or α Geminorum, as the components seem to have been behaving rather differently from what computation has destined them. The orbit, which was calculated in 1877, seems to have been entirely upset by the fact that since 1887 the components have been steadily approaching each other. With the assistance of Mr. J. I. Plummer, Prof. Doberck has collected all available observations and compared them with computed elements (*Astr. Nachr.*, 2168). From this he has formed the normal places, which have led him to obtain the following elements referred to the year 1900 :—

$$\Omega = 33^\circ\ 0' \qquad e = 0{\cdot}5909$$
$$\gamma = 69\ \ 34 \qquad P = 318{\cdot}23 \text{ years}$$
$$\lambda = 87\ \ 14 \qquad T = 1948{\cdot}86$$
$$a = 6''{\cdot}605$$

From these Prof. Doberck has calculated an ephemeris for the apparent places for the years 1900–1920, from which we make the following extract :—

t.	Pos. angles θ	Dist. ς	$\Delta\alpha$	$\Delta\delta$
	°	"	s	"
1900	225·65	5·644	−0·310	−4·04
1901	225·22	5·625	−0·312	−4·00
1902	224·78	5·603	−0·313	−3·95
1903	224·34	5·579	−0·314	−3·90
1904	223·89	5·554	−0·315	−3·85
1905	223·44	5·527	−0·315	−3·80

THE INTERNATIONAL CONFERENCE ON TERRESTRIAL MAGNETISM.

WE publish below the more essential parts of the Report of the Permanent International Committee on Terrestrial Magnetism. That report will, we believe, be submitted to the Committee of the International Meteorological (and Magnetic) Conference, to be held next summer in St. Petersburg, and may be referred by them to the full meeting of the Conference to be held in 1900 or 1901. The decisions arrived at will thus be fully considered on several occasions, and will probably command universal acceptance when they are finally approved.

It is unnecessary to discuss in detail the four points which were submitted to the Committee by the Paris Conference. Two of these refer to the form in which the observations made at observatories should be published. A third, based on a report by M. Mascart, is, no doubt, intended to crush the curious superstition, which still prevails, to the effect that the larger the magnet employed to measure the magnetic elements the more accurate will be the results attained.

The fourth point referred to the Committee was of more importance. The whole science of Terrestrial Magnetism is waiting for more accurate knowledge of the magnetic state of the earth in the tropics and the southern hemisphere. The Committee propose that temporary observatories shall be established at some dozen different places, most of which are easily accessible, and, if possible, maintained during a sun-spot cycle. This can only be done by international co-operation, and it is to be hoped that the scheme may be carried out before long; more especially as the report on which the resolution was founded was jointly prepared by General Rykatcheff and Prof. von Bezold, who hold high official scientific positions in Russia and Germany respectively.

The other papers read before the Conference were devoted to various subjects which fairly covered the whole range of the science.

Prof. Adams' account of his brother's calculations on the Gaussian constants, and Prof. Schuster's paper on a similar subject, led to the remark that the mathematics of the subject were at present far ahead of the accuracy of our knowledge of the facts to which they are to be applied.

The announcement made by Dr. Schott that a magnetic observatory was about to be established in Honolulu, the steps taken by the Prince of Monaco to found an observatory in the Azores, and the plucky start made by Dr. Beattie and Mr. Morrison in a magnetic survey of South Africa, were sufficient proof that efforts are being made to bring our experimental facts to the standard our mathematics have attained.

Local disturbances were dealt with in Sig. Palazzo's paper on the neighbourhood of Etna, and in Captain Creak's interesting statement as to the island of Funafuti. As our readers are aware, this is the coral island on which boring operations have been carried on for some time in order to test the rival theories of the origin of atolls. The magnet has to a certain extent anticipated the results to be obtained by the drill. Indubitable evidence has been found that the island is a centre of magnetic attraction, and the magnitude of the vertical disturbance indicates the presence of highly magnetic rock. It is, of course, possible that this may exist at a depth which no boring could reach; but the result is certainly of interest with reference to the problem which the boring is intended to solve.

Drs. van Rijckevorsel and Bemmelen announced that their elaborate survey of the Rigi had failed to establish any definite connection between the magnitude of the magnetic elements and height above the sea level. Earth currents were dealt with by Prof. Schuster and Dr. Lemström. Dr. Schmidt utilised the occasion to enforce the fact that isolated observations, made at irregular intervals, at ill-defined positions, are of little use in the determination of the secular change; while Dr. Eschenhagen pleaded for the co-operation of other observers in the simultaneous observation of the minute magnetic disturbances of which he is virtually the discoverer.

The Conference on the magnetic and electrolytic disturbances produced by electric railways was not well attended by electrical engineers, but the fact that Mr. Preece and Prof. Fleming were on the side of those who insist that these evils shall be dealt with while they are still in their infancy, gives hope that the bitter cry which is going up from directors of observatories, all the world over, will not be unheeded.

It only remains to add that the improvements in the organisation of the Permanent Magnetic Committee, which were advocated by the President in his opening address, were adopted by the Committee; and that the Magnetic Section of the International Meteorological Conference will probably in future be far more important than it has been in the past.

REPORT OF THE PERMANENT COMMITTEE ON TERRESTRIAL MAGNETISM AND ATMOSPHERIC ELECTRICITY TO THE INTERNATIONAL METEOROLOGICAL CONFERENCE.

Constitution of the Committee.

I. The Committee on Terrestrial Magnetism and Atmospheric Electricity appointed at Paris in September 1896, consisted of eight members. These gentlemen found that it was desirable to add to their number, by co-option, and the constitution of the Committee is now as follows:—

Appointed at Paris: Prof. Rücker (President), Prof. Eschenhagen, Prof. Liznar, M. Th. Moureaux, Sig. L. Palazzo, Dr. Paulsen, Dr. van Rijckevorsel, General Rykatcheff.

Co-opted: Dr. Bauer, Prof. W. von Bezold, Sig. Brito-Capello, Dr. Carlheim-Gyllenskjold, Prof. Mascart, Prof. T. Mendenhall, Prof. A. Schmidt, Dr. C. Schott, and Prof. A. Schuster.

The report then proceeds to give an account of the proceedings of the Conference at Bristol, which have been described in these columns.

II. Dr. C. H. Lees, of the Owens College, Manchester, and one of the Secretaries of the Section of Mathematics and Physics of the British Association, acted as Secretary of the International Conference and of the Permanent Committee.

Meetings of the Permanent Committee.

III. During the session of the British Association, the Committee also held meetings on September 7, 9, 12 and 13, at which the following resolutions were unanimously approved:—

(*a*) Matters referred to the Committee by the International Meteorological Conference.

Four questions were referred to the Committee.

The first of these was the following resolution of M. Dufour (Report of the Paris Conference, p. 30).

> "In calculating monthly means, all days are to be taken into consideration. It is left open to each Director to give, in addition, means calculated without taking disturbed days into account."

This was approved by the Committee with the substitution of the words "It is desirable" for the words "It is left open to each Director."

(1*a*) The Committee were also of opinion that the quiet days chosen by the Directors of the different observatories should be communicated to the President of the Permanent Magnetic Committee, and circulated by him, and also that it is desirable to inquire if it will be possible to select the same quiet days for the different observatories.

(2) The second resolution referred to the Committee was the following, proposed by Prof. von Bezold and M. Mascart (Report, p. 31).

> "It is desirable to publish the monthly means of the components X, Y, Z, and at least for the months of January and July, the differences dX, dY, dZ, of the hourly means from the preceding means."

In lieu of this the Committee adopted the following resolution:—

> "It is desirable to publish the monthly means of the Geographical Components of the Magnetic Force for each month, and also the differences between the hourly means for each month, and the monthly means for that month."

(3) The third resolution referred to the Committee was the following, proposed by General Rykatcheff (Report, p. 32).

> "It is desirable for the progress of Terrestrial Magnetism that temporary observatories should be installed in certain localities, especially in tropical countries."

On this subject a report had been prepared at the request of the President, by Prof. von Bezold and General Rykatcheff, of which a copy is appended.

After considering the report the Committee resolved:—

> "That it is desirable that temporary magnetic observatories should be established in places such as the following:—Taschkent, Peking, the Lick Observatory, Quito, Para, Colombo, Cape of Good Hope, St. Paul or N. Amsterdam, Honolulu, and Point Barrow or Sitka, or some other station in a high latitude in North America."

"That these observatories should, if possible, be provided with both absolute and variation instruments, of which the latter should be self-registering instruments, and should be established for at least seven, and if possible, for eleven or twelve years, *i.e.* for a complete sun-spot period."

The Committee were informed by Dr. C. Schott that it was the intention of the Coast and Geodetic Survey of the United States to establish a magnetic observatory at Honolulu.

In the course of the discussion on the above resolution, the Committee also resolved :—

(3*a*) "That it is desirable to point out that observatories at great distances from others should be provided with both absolute and self-registering variation instruments."

(4) The fourth matter referred to the Committee was the question as to the relative advantages of long and short magnets, raised by M. Mascart at the Paris Conference (Report, p. 39).

On this subject a report, of which a copy is appended, had been prepared, at the request of the President, by M. Mascart.

After considering this report, the Committee resolved :—

"Unless special reasons exist to the contrary it is desirable that the dimensions of the magnets should be as small as possible, provided that the accuracy of the results is adequately maintained."

(*b*) Resolutions passed by the Committee on matters arising during the International Conference.

(5) Prof. Eschenhagen made a statement to the Conference as to his recent investigations on minute disturbances made by very sensitive apparatus with a very open time scale.

In view of this statement, the Committee expressed their sense of the importance of the resolutions on this subject passed by the Paris Conference (Report, p. 35), and the hope that the principal observatories would carry out simultaneous observations of the character proposed.

M. Moureaux informed the Committee that preparations for such observations were already complete in the observatory at Parc St. Maur.

The Committee took note of the statement that Prof. Eschenhagen would be willing to give information as to the construction of the instruments used by him.

(6) The Committee also passed the following resolution :—

"The Committee is of opinion that the early establishment of a magnetic observatory at the Cape of Good Hope, provided with absolute and self-registering variation instruments, would be of the highest utility to the science of Terrestrial Magnetism, especially in view of the Antarctic expeditions which are about to leave Europe, and that the observatory should be established at such a distance from electric railways and tramways as to avoid all possibility of disturbance from them."

Directions were given that the proper steps should be taken to obtain the approval of the British Association for this resolution, with the request that, if approved, it should be forwarded to the Colonial Government.

(7) On the motion of Prof. Adolph Schmidt, the Committee resolved :—

"That it is desirable that magnetic observations taken in regions not included in a magnetic survey, should be repeated from time to time, care being taken to secure the identity of the point of observation."

(8) Prof. Eschenhagen was requested to draw up a detailed scheme for the exchange between the various observatories of the curves of the self-registering variation instruments taken during important magnetic storms, and to lay the scheme before the next meeting of the Conference.

(9) With reference to certain inquiries which Prof. Eschenhagen suggested should be addressed to the Directors of Magnetic Observatories, the Committee was of opinion that, although it would be outside the scope of their duties to make the inquiries, it was desirable that the information should be collected and published.

(10) After the discussion on the magnetic disturbances introduced by electric railways and tramways, the following resolution was adopted by the Committee :—

"The Committee are of opinion that any sensible magnetic disturbance produced in a magnetic observatory by electric railways or tramways, is seriously detrimental and may be fatal to the utility of the observatory. They consider that special precautions should be taken to prevent such disturbances, and append as an example the provisions for the protection of the Kew Observatory, inserted in a Bill passed by the British Parliament authorising the construction of an electric railway, the nearest point of which is to be at a distance of one kilometre from the observatory (Appendix II.)."

Future Organisation of the Committee.

(10) The Committee took into consideration their own future organisation, and passed the following resolutions :—

"It is desirable that terrestrial magnetism should continue to be within the scope of the International Meteorological Conference, provided that :—

(*a*) Invitations to attend that Conference are issued as widely as possible to Directors of Magnetic Observatories and to all students of Terrestrial Magnetism.

(*b*) That the Permanent Committee on Terrestrial Magnetism and Atmospheric Electricity, as established at the Paris Conference, be continued.

(*c*) That in future there shall be a magnetic section of the International Meteorological Conference, which shall elect, or otherwise share in the appointment of, a permanent Magnetic Committee.

(*d*) That the Magnetic Committee have power to summon an International Magnetic Conference at times other than those at which the whole of the International Meteorological (and Magnetic) Conference may meet."

The Committee also consider that the President of the Permanent Magnetic Committee should hold office between two successive meetings of the International Meteorological (and Magnetic) Conference.

(Signed) Arthur W. Rücker, *President.*

September 13, 1898.

Appendix II.

Clause for the protection of Kew Observatory.

(1) The whole circuit used for the carrying of the current to and from the carriages in use on the railway shall consist of conductors which are insulated along the whole of their length to the satisfaction in all respects of the Commissioners of Her Majesty's Works and Public Buildings (in this section called "the Commissioners"), and the said insulated conductors which convey the current to or from any of such carriages shall not at any place be separated from each other by a distance exceeding one hundredth part of the distance of either of the conductors at that place from Kew Observatory.

(2) If in the opinion of the Commissioners there are at any time reasonable grounds for assuming that by reason of the insulation or conductivity having ceased to be satisfactory a sensible magnetic field has been produced at the observatory, the Commissioners shall have the right of testing the insulation and conductivity upon giving notice to the Company, who shall afford all necessary facilities to the engineer or officer of the Commissioners or other person appointed by them for the purpose, and the Company shall forthwith take all such steps as shall in the opinion of the Commissioners be required for preventing the production of such field.

(3) The Company shall furnish to the Commissioners all necessary particulars of the method of insulation proposed to be adopted, and of the distances between the conductors which carry the current to and from the carriages.

APPLICATIONS OF ELECTRICITY.[1]

Lightning.

THE first practical application of the science of electricity was for the protection of life and property. Franklin in 1752 showed how to secure ourselves and our buildings from the disastrous effects of a lightning stroke. Very little has been done since to improve upon his plan. A Lightning-Rod Conference, upon which I served, met in 1878, and its report, published in 1881, remains an admirable and useful standard of reference. The principle advocated by Franklin was prevention rather than protection. If a building or a ship be fitted and maintained with good continuous copper conductors, making a firm electrical contact with the earth or the sea, and

[1] Abridged from an inaugural address delivered at the Institution of Civil Engineers, on November 1, by the President, Mr. W. H. Preece C.B., F.R.S.

be surmounted well up in the air with one or a cluster of fine points, all the conditions that determine a charge of atmospheric electricity and a flash of lightning are dissipated silently away and no terrible discharge is possible. A mischievous and baseless delusion is prevalent that protectors actually attract lightning and may be sources of danger. Every exposed building should be fitted, but a well-protected dwelling-house is the exception not the rule. Even when protectors are fixed apathy leads to their imperfect maintenance. Their failure to act is always traceable to the neglect of some simple rule. Carelessness is the direst disease we suffer from. Telegraph and telephone wires which spread all over our towns and country are very much exposed to the influence of atmospheric electrical effects. Every instrument is now protected. Every telegraph pole has a lightning conductor. Accidents are rare, and the system itself is a public safeguard. In some countries like California and South Africa thunder-storms are very frequent and very severe, but their effects have been tamed.

TELEGRAPHY.

In 1837 Cooke and Wheatstone showed how electricity could be practically used to facilitate intercommunication of ideas between town and town and between country and country. The first line was constructed in July of that year upon the incline connecting Camden Town and Euston Grove Station, the resident engineer being Sir Charles Fox, father of the senior Vice-President. Five copper wires were embedded in wood of a truncated pyramidal section and buried in the ground. The instrument used possessed five needles or indicators to form the alphabet. A portion of this original line was recently recovered *in situ*.

The pioneer line of 1837, 1½ miles long, has, during a period of sixty years, grown into a gigantic world-embracing system. The extent of the present system of British telegraphs is shown by the following table :—

	Miles of wire.
General Post Office and its Licensees ..	435,000
Railway companies	105,000
India and Colonies	387,966
Submarine cables	183,400
Total	1,111,366

The speed of signalling and the capacity of working have been increased sixfold, and wires can now be worked faster than messages can be handled by the clerical staff.

The form of submarine cable and the nature of the materials used in its construction have varied but very little since the first cable was laid in 1851. The recent invasion of our channels and seas by the *Limnoria terebrans*, a mischievous little crustacean which bores through the gutta-percha insulating covering, and exposes the copper conductor to the sea-water, leading to its certain destruction, has led to the use of a serving of brass tape as a defence. It has proved most effective.

No one has done more than Lord Kelvin to improve the working of submarine cables. His recording apparatus is almost universally employed on long cables. By the duplex method of transmission the capacity of cables has been practically doubled, and this has been still further improved by applying to cables the system of automatic working, which is such a distinguishing feature of our Post Office system. The number of electrical impulses which can be sent through any cable per minute is dependent upon its form, and is subject to simple and exact laws, but it varies with the quality and purity of the materials used. There is no difficulty in maintaining the purity of copper. Indeed, copper is frequently supplied purer than the standard of purity adopted in this country—known as Matthiessen's standard. The purity of gutta-percha is, however, questionable. The supply of this dielectric has dwindled ; it has failed to meet the demand ; its cultivation has been neglected. The result is a dearth of the commodity, a great increase in price, and its adulteration by spurious gums. India-rubber, its sole competitor for cables, is being absorbed for waterproof garments and pneumatic tyres, but for underground purposes paper is being used to an enormous extent. Paper has the merit, when kept dry, not only of being an admirable insulator, but of being very durable. There is paper in existence in our libraries over 1000 years old. The difficulty is to keep it dry. This is one of the problems the engineer delights to consider. He has been most successful in obtaining a solution. The lead-covered paper cables, which are being laid in the streets of all our great cities, are admirable. I am laying one of seventy-six wires for the Post Office telegraphs between London and Birmingham, and the Cable Companies are contemplating leading their long cables from Cornwall up to London, so as to be free from the weather troubles of this wet and stormy island.

It is impossible to forecast the future of telegraphy. New instruments and new processes are constantly being patented, but few of them secure adoption, for they rarely meet a pressing need or improve our existing practice. The writing telegraph originating with our late member of Council, E. A. Cowper, which reproduced actual handwriting, much improved by Elisha Gray, and called the "Telautograph," is steadily working its way into practical form, and electrical type-writing machines of simple and economical form are gradually replacing the A B C visual indicator. The introduction of the telephone is revolutionising the mode of transacting business. There seems to be a distinct want of some instrument to record the fleeting words and figures of bargains and orders transmitted by telephone. Hence a supplement to that marvellous machine is needed. The telautograph and electrical type-writer will fill this want. Visions of dispensing with wires altogether have been fostered by the popularity of Marconi's "wireless telegraphy" ; but wireless telegraphy is as old as telegraphy itself, and a practical system of my own is now in actual use by the Post Office and the War Department.

TELEPHONY.

I was sent, in 1877, together with Sir Henry Fischer, to investigate the telegraph system of the American continent, and especially to inquire into the accuracy of the incredible report that a young Scotchman named Bell had succeeded in transmitting the human voice along wires to great distances by electricity. I returned from the States with the first pair of practical instruments that reached this country. They differed but little from the instrument that is used to-day to receive the sounds. The receiver, the part of the telephone that converts the energy of electric currents into sounds that reproduce speech, sprang nearly perfect in all its beauty and startling effect, from the hands of Graham Bell. But the transmitting portion, that part which transforms the energy of the human voice into electric currents, has constantly been improved since Edison and Hughes showed us how to use the varying resistance of carbon in a loose condition, subject to change of pressure and of motion under the influence of sonorous vibrations. The third portion, the circuit, is that to the improvement of which I have devoted my special attention. Speech is now practically possible between any two post-offices in the United Kingdom. We can also speak between many important towns in England and in France. It is theoretically possible to talk with every capital in Europe, and we are now considering the submersion of special telephone cables to Belgium, Holland, and Germany.

RAILWAYS.

The employment of electricity in the working of railways has not only been highly beneficent in the security of human life, but it has vastly increased the capacity of a road to carry trains. The underground traffic of the metropolis is conducted with marvellous regularity and security, though the trains are burrowing about in darkness and following each other with such short intervals of time, that the limit of the line for the number of trains has been reached. Electric traction is going to extend this limit by increasing the acceleration at starting and improving the speed of running. It will also reduce the cost of working per train-mile, so that the advent of electricity as a moving agency is certain to prove highly economical. What it will do as a remover of bad smells and foul air and for personal comfort cannot be estimated. Time alone will enable us to assess the intrinsic value of public satisfaction acquired by the change.

DOMESTIC APPLIANCES.

The introduction of electricity into our houses has added materially to the comfort and luxury of home. If we were living in the days of ancient Greece, the presiding domestic deity would have been *Electra*. The old bellhanger has been rung out by the new goddess. Electra has entered our hall-door, and attracts the attention of our domestics, not by a gamut of ill-toned and irregularly-excited bells, but by neat indicators and one uniform sound. The timid visitor fears no more that he has expressed rage or impatience by his inexperience of the mechanical pull required at the front door. The domestic telephone is coming in as an adjunct to the bell. Its

use saves two journeys. The bell attracts attention, the telephone transmits the order. Hot water is obtained in half the time and with half the labour. Fire and burglar alarms are fixed to our doors and windows; clocks are propelled, regulated and controlled. Even lifts are hoisted for the infirm and aged. Ventilation, and in warmer countries coolness, are assisted by fans. Heating appliances are becoming very general where powerful currents are available. Radiators assist the coal fire by maintaining the temperature of a room uniform throughout its length and breadth. Ovens are heated, water is boiled, flat-irons become and are maintained at a useful temperature, breakfast dishes and tea-cakes are kept hot, even curling-tongs have imparted to them the requisite temperature to perform their peculiar function.

Electric Light.

But it is in supplying us with light without defiling the air we breathe in our dwellings with noxious vapour, that electricity has proved to be a true benefactor to the human race. The Legislature has facilitated the acquisition by municipalities of those local industries that affect the welfare of the whole community, such as road-making, sewerage, the supply of water, tramways, and, above all, electric light.

It is on board ship that electric light has been pre-eminently successful, and where it filled such a crying want that its introduction met with no check. It was almost immediately and universally adopted. Search lights, prompted by the great development of the torpedo, were introduced into our Navy as early as 1875 by Mr. Henry Wilde. The first ship to be fitted with internal electric lighting was the *Inflexible* in 1882. In 1884 the Admiralty ordered it to be applied to all H.M. warships. The first application of electrical power was in the case of H.M.S. *Barfleur*, where motors were used for working guns and for the supply of ammunition. It has subsequently been partially extended to the working of gun-turrets, ventilating fans, capstans, and boat-hoisting gear; but hydraulics, the child of our venerable Past-President, Lord Armstrong, is the form still more generally preferred and used for power in our Navy, though other nations make a much more extended use of electricity. The technical reports received by the United States Navy Department indicate that the electrical appliances on their warships worked very successfully during the recent war.

Lighthouses.

The introduction of electricity into our lighthouses has not been such an unqualified success as into our ships. No new electric light has been installed on the coast of Great Britain since St. Catherine's (Isle of Wight) was fitted up in 1888. Other electric lamps are to be found at the South Foreland, at the Lizard, and at Soutar Point, only four lighthouses in all upon our coasts.

This is due chiefly to the great prime cost of its installation and to the annual expense of its maintenance. But the sailor himself is not enamoured of it. It does not assist him in judging distances. It is too brilliant in clear weather, while in bad weather it penetrates a fog no further than an ordinary oil lamp. Moreover, great modern improvements have rapidly followed each other in other apparatus, lenses and lamps. A third order light of to-day can be made superior to a first order light of ten years ago. Oils have improved and gas has been introduced. Lord Kelvin proposed that lighthouses should signal their individuality to passing ships by flashing their number in the Morse alphabet. But the Morse alphabet, in 1875, was as unknown as Egyptian hieroglyphics to our nautical authorities. The same end was obtained with less mental exertion by occulting and group-flashing systems.

A new and very promising plan has recently been introduced in France, called the "Feux-éclairs" or "lightning flash" system. It has been installed in many places, but especially at the two Capes dominating the Bay of Biscay. Nothing more brilliant or more effective is to be seen anywhere than the lights that rapidly sweep across the horizon, like well-directed flashes of summer lightning, with a motion that conveys the idea of a wave of some illuminated spirit-arm warning the navigator away from the rocky dangers of Ushant.

Our Trinity House has not yet introduced this plan. Any change of our well-considered and deeply-important coast-lightning system is not to be hastily effected. We are very proud of our well-guarded shores. Every headland and land-fall, every isolated rock, all dangerous shoals and banks and narrow channels in lines of trade are so illuminated that navigation by night is as safe and easy as by day. Lighthouses and lightships stud our channels. Most of them are placed in direct communication with our Post Office telegraph system, so that the speediest help can be secured in moments of difficulty and danger.

We, however, want improvement in fogs and storms. Here electricity steps in. I wrote, in 1893, of wireless telegraphy:— "These waves are transmitted by the ether; they are independent of day or night, of fog or snow or rain, and, therefore, if by any means a lighthouse can flash its indicating signals by electro-magnetic disturbances through space, ships could find out their position in spite of darkness and of weather. Fog would lose one of its terrors, and electricity become a great life-saving agency." We are nearing that goal.

Traction.

Electrically worked railways originated in Europe. The first experimental line was constructed by Dr. Werner Siemens in Berlin in 1879. When I visited America in 1884 there was only one experimental line at work in Cleveland, Ohio. Now there are more miles of line so worked in Cleveland alone than in the whole of the United Kingdom. The reason for this is not difficult to comprehend. The climatic influences of the States, the habits of the people, the cost of horseflesh, the necessity for more rapid transit, soon proved the vast superiority of electric over every other form of traction. Horses and cables will soon disappear. The successful progress in the States and on the Continent has proved contagious, and everywhere our great cities are rising to the occasion. The relative merits of overhead and underground conductors, and the use of storage batteries, are practically the only important engineering questions under discussion. The underground conduit system has been materially helped by the practical object-lesson to be seen in New York, where the tramways are being very successfully worked on this plan. The trolley system is much more economical. Its erection does not interfere with the traffic of the streets. The principal objection to it is its anti-aesthetic appearance, but it is wonderful how ideas of utility and the influence of custom make us submit to disfigurement. What is more inartistic than a lamp-post, or more hideous than the barn-like appearance of many a railway terminus?

The corrosion of water- and gas-pipes, the disturbances of telegraphs and magnetic observations, are serious questions arising from the introduction of powerful currents into the earth, but fortunately the remedies are simple, easily attainable, and very effective.

I have alluded to the proposed working of our underground railways. The success of the Mersey Dock line, and of the South London and Waterloo lines, have placed the question beyond controversy. The problem to be solved is how is the conversion from steam to electricity to be effected without interfering in any way with the existing traffic or with the existing permanent way? This is not to be solved on paper. It must be determined by actual trial, and this is about to be done on the short line connecting Earl's Court and High Street, Kensington. Electric traction as an economical measure in all cases of dense traffic is so certain that every great railway company must consider, sooner or later, the working of their surburban traffic by electricity. This experiment on the Metropolitan Underground Railways, therefore, should interest them all. It is a question deeply affecting the interests and comfort of the public and the condition of the congested traffic of our streets.

The storage battery fulfils a very important function in the economical working of an electric railway. It equalises the pressure on the circuits. It meets the fluctuations of the load. It takes in current when the load is light; it lets out current when the load is heavy. It thus secures the continuous working of the engines at their full constant and most economical conditions, and it enables the engines to be shut down altogether when the load is very light, as it is at night, in the early morning, and on Sundays.

In Buffalo the battery is charged by energy from Niagara, twenty-one miles away, and the local engines are shut down for twelve hours every day, and for ten hours on Sunday.

Electro-Chemistry.

The transference of electricity through liquids is accompanied by the disintegration of the molecules of the liquids into their constituent elements. The act of conduction is of the nature of

work done. Energy is expended upon the electrolyte to break it up, and the quantity thus chemically decomposed is an exact measure of the work done. Every electrolyte requires a certain voltage to overcome the affinity between its atoms, and then the mass decomposed per minute or per hour depends solely upon the current passing. The process is a cheap one and has become general. Three electrical HP. continuously applied deposit 10 lbs. of pure copper every hour from copper sulphates at the cost of one penny. All the copper used for telegraphy is thus obtained. Zinc in a very pure form is extracted electrolytically from chloride of zinc, produced from zinc blende, in large quantities. Caustic soda and chlorine are produced by similar means from common salt. The electroplating of gold, silver and nickel is a lucrative and extensive business, especially in Birmingham and Sheffield. Gold and silver are refined by this electrolysis in Russia, and nickel in the United States. Sea-water is decomposed in this way for disinfecting purposes by the Hermite process.

The passage of electricity through certain gases is accompanied by their dissociation and by the generation of intense heat. Hence the arc furnace. Aluminium is thus obtained from cryolite and bauxite at Foyers by utilising the energy of the Falls. Phosphorus is also separated from apatite, and other mineral phosphates. Calcium carbide, obtained in the same way, is becoming an important industry.

It is remarkable that our coalfields have not been utilised in this direction. Electrical energy can be generated on a coal-field, where coal of good calorific value is raised at a cost of 3*s.* per ton, cheaper than by a waterfall, even at Niagara.

Electro-metallurgy is now a very large business, but it is destined to increase still more, for the generation of electrical energy is becoming better understood and more cheaply effected.

The Transmission of Power.

The energy wasted in waterfalls is enough to maintain in operation the industries of the whole world. Great cities as a rule are not located near great falls; nor has a beneficent Providence provided great cities with waterfalls as, according to the American humourist, He has with broad rivers. There is but one Niagara, and we are seeing how industries are rather going to the falls than the energy of the falls is being transmitted to the industrial centres. The arbitrament of money is limiting the distance to which energy can be profitably transmitted. The Cataracts of the Nile can be utilised in irrigating the waste lands of the upper regions of the river, but their energy cannot compete, at Alexandria, with that of coal transported in mass from England.

At Tivoli, fifteen miles across the Campagna, the energy of the falls are economically utilised to light Rome and to drive the tramways of that city. The electric railways at Portrush and Bessbrook, in Ireland, are worked by water-power, and Worcester, Keswick and Lynton use it in this country, but on a very small scale. It is not used more, for the simple reason that there are no more falls to use. Water-power is used very extensively in Switzerland, because it is so abundant there, and in our Colonies, especially in South Africa; but it is in the United States, especially in Utah and California, where the greatest works have been installed especially for the transmission of energy to mines.

In mines electricity is invaluable. It is used for moving trams and for working hoists. It lights up and ventilates the galleries, and by pumping keeps them free of water. It operates the drills, picks, stamps, crushers, compressors, and all kinds of machinery. The modern type of induction motor, having neither brushes nor sliding contacts, is free from sparks and safe from dust. Electrical energy is clean, safe, convenient, cheap, and it produces neither refuse nor side products. It is transmitted to considerable distances. In mountainous countries the economical distance is limited by the voltage which insulation can resist; 40,000 volts are being practically used between Provo Canyon and Mercur, in Utah, in transmitting 2000 horse-power thirty-two miles.

Conclusion.

I have touched lightly—I fear too lightly—upon some of the applications of electricity. I have confined myself, in a very general sense, to those with which I have been personally associated. I have shown how electricity began its beneficent career by protecting our lives and property from the disastrous effects of nature's dread artillery, how it facilitates intercommunication between mind and mind by economising time and annihilating space. It

> "Speeds the soft intercourse from soul to soul,
> And wafts a sigh from Indus to the Pole."

By its metallic nerves it brings into one fold not only the scattered families of one nation, but all countries and all languages, to the manifest promotion of peace and general good will. Not only does it show us how to utilise the waste energies of nature, but it enables us to direct them to the place where they are most wanted and to use them with the greatest economy. It opens to our view nature's secret storehouses, presenting us with new elements, new facts and new treasures. It economises labour and purifies material. It lightens our darkness in more senses than one, and by enabling us to see the unseen, it tends to aid the gentle healing art and to alleviate both suffering and pain. It aids us in the pursuit of truth, and it has exploded the doctrine that the pursuit of truth means the destruction of faith.

RECENT CORAL BORING OPERATIONS AT FUNAFUTI.

The subjoined extract from the *Sydney Daily Telegraph* of September 9, containing particulars as to the coral-boring operations at Funafuti, has been sent to us by a correspondent:—

News has just been received *via* New Zealand, through the U.S.S. Co.'s steamer *Poherua*, which coaled H.M.S. *Porpoise* at Funafuti, as to the progress of the two bores, one on land, and the other in the lagoon of that coral atoll. With regard to the lagoon bore, operations were commenced on August 15, Commander Sturdee having succeeded in mooring the war-ship so taut that it was possible to work the boring pipes without risk of their bending or breaking from the bows of the war-ship. Mr. G. H. Halligan, who is in immediate charge of the boring plant, reports that for the first twenty-four hours of boring a depth of 109 feet was attained, the total depth of the bore being 212 feet below the water level of the lagoon, the depth of water to the bottom of the lagoon being 103 feet. The *Poherua* left at the end of the first day's boring. As regards the nature of the material bored, Mr. Halligan states that the first 80 feet below the bottom of the lagoon were formed of sand, composed of joints of Halimeda (a seaweed which secretes a jointed stem of lime) and of fragments of shells. The remaining 29 feet were in similar material, but containing small fragments of coral getting larger at the deeper levels.

This is a record rate of boring, and considering the difficulty of holding the war-ship at her moorings absolutely steady, in spite of wind and tide, is a wonderful performance. The whole undertaking may be looked upon as a success from a scientific standpoint, even if no greater depth than 109 feet be ultimately reached. As, however, there was still nearly a week available for further boring, it is hoped that before the war-ship has to leave Funafuti, the bore may have been considerably deepened. This is probably the first bore that has ever been made in the bottom of the lagoon of a coral atoll.

The deepening of the old bore, discontinued last year at a depth of 698 feet, on the main island of Funafuti, has been proceeding slowly but steadily. The party were landed there by the London Missionary Society's steamer *John Williams*, on June 20 last. As was anticipated, little difficulty was experienced in re-driving the lining pipes into the old bore, and washing out the sand and rubble which had choked the bore-hole. Pipes were laid from the site of the old bore to some small water-holes from which a supply of fresh water was obtained for the boiler. By July 25, the re-lining and cleaning of the old bore having been successfully accomplished, boring was resumed, and up to the time when the steamer *Poherua* left, a depth of 840 feet had been reached. The bore last year terminated in soft dolomite limestone at 698 feet, but it has now been ascertained that below this is a hard rock, so hard that the portion of the bore-hole which penetrates it no longer needs to be lined with iron pipes, a condition which must facilitate the work of boring.

Mr. A. E. Finckh reports that this hard rock is largely composed of corals and shells. This depth of 840 feet is exactly the crucial depth which it was hoped the bore might reach, and if possible exceed, as at a corresponding depth on the ocean face of the reef there is a strongly marked shelf, as shown by the soundings by Captain A. Mostyn Field, of H.M.S. *Penguin*,

and it is considered that this shelf, at the 140 fathoms level, marks the downward limit of the coral formation.

Exceptionally dry weather has been experienced, which has somewhat delayed the boring, on account of the temporary failure of the water-hole from which the water supplies were being drawn. Foreman Symons, however, who is in charge of the drill, had, by extending the line of suction pipes, been able to tap a second water-hole, from which water was being pumped to the boiler. Mr. Finckh's experiments on the rate of growth of the various reef-forming animals and plants were progressing satisfactorily. It was hoped that the bore would, in about eight weeks' time, reach the total depth of 1200 feet, which is the maximum depth contemplated. Further information may be expected shortly upon the return from Funafuti of H.M.S. *Porpoise*, which will convey all the core hitherto obtained from Funafuti, and tranship it to Sydney; and until the core has been subjected to thorough microscopic and chemical examination it would, of course, be premature to attempt to forecast the exact trend of the evidence. The results so far obtained are very satisfactory.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. Langley, F.R.S., has been elected a member of the Council of the Senate in the place of Principal Glazebrook, now of Liverpool University College.

Lord Wolsingham, the High Steward, has generously offered a second (bronze) medal for specially meritorious essays in biology which do not succeed in winning the Wolsingham gold medal.

At the matriculation on October 21 last, 897 students joined the University. These included 19 "advanced students" admitted to post-graduate research or other advanced work. The total entry for the year 1898 is thus brought up to 944, which is the highest since 1890.

An animated discussion on the proposed Sedgwick Memorial Museum took place in the Arts School on October 22. Two plans, a larger and a smaller, were before the Senate. The geological staff strongly pressed that the larger should be adopted, though it appeared that it would cost some 44,000*l*. Of this the Memorial Fund would contribute 27,000*l*.

Mr. R. S. Morrell, who was placed in the first class in both parts of the Natural Sciences Tripos in 1888-90, and Mr. J. S. Gardiner, who was similarly placed in 1893-95, have been elected to Fellowships at Gonville and Caius College.

ON Wednesday, October 26, Sir William Harcourt opened the new central block of Aberystwith University College, erected at a cost of about 20,000*l*., towards which sum he, when Chancellor of the Exchequer, gave a grant of 10,000*l*. Speaking subsequently at a luncheon, Sir William Harcourt referred to the unsatisfactory state of secondary or intermediate education in England, and said that what was required was a system of intermediate education similar to that which has been established in Wales, to connect the elementary schools with the universities.

SPEAKING at University College, Liverpool, on Friday last, Sir J. Gorst, Vice-President of the Committee of Council on Education, said that at the present time there was a strong desire on the part of all interested in education that a great step forward should be made in commercial and technical instruction. The necessity arose from industrial competition in foreign countries. Undoubtedly our higher and elementary education for industrial purposes was vastly inferior to that of many of our rivals, and no time was to be lost in setting to work to effect an improvement. To this forward step there were two essential conditions. In the first place, elementary education must be improved, for it was no use to attempt to organise a system of higher schools without having a sound elementary basis upon which to build. Moreover, it was essential that higher education should be perfectly organised, and that in each educational area there should be one clear and definite plan of education suitable to the particular conditions of the place.

THE report on the work of the Examinations Department of the City and Guilds of London Institute for the session 1897-98 has been published. From it we learn that the number of technical classes throughout the country registered by the Institute shows a marked increase, and the instruction is in closer touch with industrial requirements. The recognition by the Post Office of the Institute's certificate in telegraphy as qualifying the holder of it for increased remuneration has had the effect of nearly doubling the number of candidates for examination in that subject, and shows the influence, which employers generally might exercise, in encouraging attendance at technical classes, by giving some kind of reward to such of their employés as succeed in passing the Institute's examinations. County Councils have during the past year further availed themselves of the services of the Institute in connection with the technical classes under their control. Several important additions and alterations have been made in the programme of Technological Examinations.

THE Calendar of the University College of North Wales (which is a constituent College of the University of Wales) for the year 1898-99, has been published. The syllabus of classes shows that students are educated as well as instructed at the College, and the questions set in the science subjects in which candidates for entrance scholarships have been examined, give evidences that no credit is gained by perfunctory work or for information derived entirely from books. The College offers a course of training to those who intend to become teachers in secondary or intermediate schools, and in this, as in other subjects, the course involves practical as well as theoretical work. Among the subjects to be dealt with in the lectures are the psychology of the growing mind, and physiology and hygiene in their relation to school life. The agricultural department, and the College Farm, have recently been referred to (p. 611). After following a course of study at the College extending over three years, students may take the degree of Bachelor of Science of the University of Wales in the group "Agriculture and Rural Economy."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 24.—M. Wolf in the chair.—On double integrals of the second species in the theory of algebraic surfaces, by M. Émile Picard.—Properties of calcium, by M. Moissan. The pure crystallised calcium whose properties are given in this paper, was prepared by the method already described in NATURE. The melting point, determined by a thermo-couple, was found to be 760° C. The metal can be cut, but it is much less malleable than sodium or potassium, as it can be broken, and shows a crystalline fracture. When totally free from nitride, its colour is brilliantly white, recalling that of silver. The density was found to be about 1·85; and it is hard enough to scratch lead, but not calcium carbonate. Neither chlorine, bromine, nor iodine attacks calcium in the cold, although the corresponding haloid salts are formed at higher temperatures. Calcium burns brilliantly in oxygen, the temperature resulting from the combustion being so high that a part of the quicklime produced is melted and volatilised. When burnt in air, the calcium combines with both constituents together, nitride and oxide being simultaneously formed. At a dull red heat the metal also combines with carbon with great energy, forming CaC_2. At high temperatures the reducing power of calcium is remarkable, oxygen being readily removed from sulphur dioxide, phosphoric anhydride, boron trioxide, silica, and the oxides of carbon.—On the decomposition by aluminium chloride, of a straight-chain saturated hydrocarbon, by MM. C. Friedel and A. Gorgeu. The reactions have been studied arising between aluminium chloride and the normal paraffins from methane to hexane. The latter, when heated to its boiling point with dry $AlCl_3$ gave rise to pentane and butane, the pentane predominating.—On a peculiar mode of formation of the pollen in *Magnolia*, by M. L. Guignard. As regards the mode of formation of the partitions in the pollen mother-cell, the *Magnolia* present a condition quite unknown in other plants. They are intermediate between Monocotyledons and Dicotyledons, resembling rather the former than the latter.—Extension of No. 162 of the "Disquisitiones Arithmeticae" of Gauss, by M. de Jonquières.—Remarks by M. Hatt on the new portion of the hydrographic map of the coasts of Corsica.—Observations of the new Brooks' comet (October 20, 1898), made at the Observatory of Paris, by M. G. Bigourdan.—On the intermediate integrals of equations of the second order, by

M. E. Goursat.—On singular points situated on the circle of convergence, and on the summation of divergent series, by M. Leau.—Measurement of the velocity of sound, by M. Frot. The experiments were made near Bourges, at a temperature near 0° C., the time being measured automatically by electric chronographs. Two sets of experiments gave for the velocity in air at 0° mean results of 330·6 and 330·9 metres per second.—On the tones of vibrating strings, by M. A. Guillemin. By suitably fixing any portion of a vibrating string any desired overtone can be produced; but this does not in any way prove that this note really existed as a partial tone in the original note given by the string. — On the atomic weight of tellurium, in relation to the multiple proportions of the atomic weights of other simple bodies, by M. H. Wilde.—On the positions of tellurium and iodine in periodic systems of the elements, by M. H. Wilde. Remarks on the recent determination by Metzner of the atomic weight of tellurium (128) as invalidating the periodic arrangements of Mendelejeff, Crookes and others.—On calcium amalgam, by M. J. Ferée.—Action of metallic sulphates on potassium paratungstate, by M. L. A. Hallopeau.—On the amines and amido-derivatives of the aldehydes, by M. Marcel Delépine. A thermochemical paper.—On the changes in composition which take place in fatty seeds in the course of germination, by M. L. Maquenne. The oily materials in the seeds of the earth-nut and castor-oil plant undergo a rapid diminution during germination, the latter being especially marked in this respect, the change being accompanied by an increase in carbohydrates.—Contribution to the biology of wine yeasts, by M. J. A. Cordier. The appearance of *Saccharomyces* upon fruit, especially the grape, at the period of ripening, has hitherto been described as due to the action of insects, but it would appear from the experiments quoted that the air is really the principal factor in the transport of these yeasts.—The specific characters of *Endomyces albicans*, by M. Paul Vuillemin.—On the place of the Phoronidiae in the classification of animals, and on their relations with the vertebrates, by M. Louis Roule.—On the respiratory apparatus of the larvae of entomophagous Hymenoptera, by M. L. G. Seurat. It is shown that the respiratory apparatus of the different larvae of entomophagous Hymenoptera, although all built on the same fundamental plan, present differences in the number and arrangement of some of their parts, sufficient to establish distinctive characters of the several families. There is not yet sufficient knowledge, however, to draw any general conclusions.—On an organ, not previously described, which closes the poison reservoir in ants, and on the method of stinging in the same, by M. Charles Janet.—New observations on the cave and subterranean river of Han-sur-Lesse (Belgium), by M. Martet. The paper is accompanied by a plan and section of the cave and stream. The unknown part of its course is now only two kilometres.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 3.

CHEMICAL SOCIETY, at 8.—A Determination of the Equivalent of Cyanogen: George Dean.—Note on the Action of Light on Platinum, Gold, and Silver Chlorides: E. Sonstadt.—Methanetrisulphonic Acid; E. H. Bagnall.—A Composite Sodium Chlorate Crystal in which the Twin Law is not followed: W. J. Pope.—On the Composition of American Petroleum: Dr. Sydney Young, F.R.S.—(1) On the Separation of Normal and Iso-heptane from American Petroleum; (2) On the Action of Fuming Nitric Acid on the Paraffins and other Hydrocarbons: Dr. F. E. Francis and Dr. Sydney Young, F.R.S.—On the Boiling Points and Specific Gravities of Mixtures of Benzene and Normal Hexane: D. H. Jackson and Dr. Sydney Young, F.R.S.

LINNEAN SOCIETY, at 8.30.—On *Craterostigma pumilum*, Hochst.: Prof. H. Marshall Ward, F.R.S., and Miss Dale.—Amphipoda from the Copenhagen Museum and other Sources, Part II: Rev. T. R. Stebbing, F.R.S.—Exhibitions: Embryos of *Hatteria*: Prof. Howes, F.R.S.—Photographs of Chicken with Foster-Parent a Common Buzzard: Alan F. Crossman.—*Nitella hyalina*, Ag., a New British Plant: H. and J. Groves.

FRIDAY, NOVEMBER 4.

GEOLOGISTS' ASSOCIATION, at 8.—Conversazione and Exhibition of Specimens.

QUEKETT MICROSCOPICAL CLUB, at 8.

TUESDAY, NOVEMBER 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Extraction of Nickel from its Ores by the Mond Process: Prof. W. C. Roberts-Austen, C.B., F.R.S.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—The Tribes inhabiting the Mouth of the Wanigela River, New Guinea: R. E. Guise.

WEDNESDAY, NOVEMBER 9.

GEOLOGICAL SOCIETY, at 8.—On the Palæozoic Radiolarian Rocks of New South Wales: Prof. T. W. Edgeworth David and E. F. Pittman.—On the Radiolaria in the Devonian Rocks of New South Wales: Dr. G. J. Hinde, F.R.S.

THURSDAY, NOVEMBER 10.

MATHEMATICAL SOCIETY, at 8.—Some Secondary Needs and Opportunities of English Mathematicians: Presidential Address.—The Structure of certain Linear Groups with Quadratic Invariants. Dr. L. E. Dickson.—Multiform Solutions of certain Differential Equations of Physical Mathematics and their Applications: H. S. Carslaw.—A Discovery in the Theory of Compound Partitions: Major Macmahon, R.A., F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Rotatory Converters: Prof Silvanus P. Thompson, F.R.S.

FRIDAY, NOVEMBER 11.

ROYAL ASTRONOMICAL SOCIETY, at 8.

PHYSICAL SOCIETY, at 5.—Discussion on Mr. A. Campbell's Paper on the Magnetic Fluxes in Meters and other Electrical Instruments, to be opened by Prof. W. E. Ayrton, F.R.S.—On the Propagation of Damped Electrical Oscillations along Parallel Wires: Prof. W. B. Morton.—On the Properties of Liquid Mixtures: R. A. Lehfeldt.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Domestic Hygiene: Dr. A. W. Williams (Bell).—A Manual of the Grasses of New South Wales: J. H. Maiden (Sydney, Gullick).—Manual of Bacteriological Technique and Special Bacteriology: T. Bowhill (Edinburgh, Oliver).—The Teacher's Manual of Object Lessons in Domestic Economy: V. T. Murchè, Vol. 2 (Macmillan).—Electricity made Easy: Drs. Houston and Kennelly (Sonnenschein).—Algebra made Easy: Drs. Houston and Kennelly (Sonnenschein).—The Interpretation of Mathematical Formulae: Drs. Houston and Kennelly (Sonnenschein).—A Pocket Dictionary of Electrical Words, Terms, and Phrases: Dr. E. J. Houston (Sonnenschein).—Organic Evolution Cross-Examined: Duke of Argyll (Murray).—The Groundwork of Science: Dr. St. Geo. Mivart (Murray).—The Natural History of Digestion: Dr. A. L. Gillespie (W. Scott).—Graham-Otto's Ausführliches Lehrbuch der Chemie, Erster Band, Dritte Abthg. (Braunschweig, Vieweg).—University College, Nottingham, Calendar 1898–99 (Nottingham, Sands).—An Introduction to Practical Physics: D. Rintoul (Macmillan).—The Egyptian Soudan: its Loss and Recovery: Lieuts. Alford and Sword (Macmillan).—L'Art de Découvrir les Sources et de les Capter (Paris, Baillière).—Marvels of Ant Life: W. F. Kirby (Partridge).

PAMPHLETS.—Lessons in Domestic Science: E. R. Lush, Part 2 (Macmillan).—Ein Ausflug auf den Aetna: A. Belar (Laibach, Kleinmayr).

SERIALS.—Longman's Magazine, November (Longmans).—Good Words, November (Isbister).—Sunday Magazine, November (Isbister).—Journal of the Royal Statistical Society, September (Stanford).—Transactions of the Institution of Engineers and Shipbuilders in Scotland, October (Glasgow).—Record of Technical and Secondary Education, October (Macmillan).—Chambers's Journal, November (Chambers).—Century Magazine, November (Macmillan).—Humanitarian, November (Duckworth).—National Geographic Magazine, October (Washington).—Physical Review, August (Macmillan).—Contemporary Review, November (Isbister).—Journal of the Royal Microscopical Society, October (20 Hanover Square).

THURSDAY, NOVEMBER 10, 1898.

AN IRISH ALGEBRA.

The New Explicit Algebra in Theory and Practice: for Teachers and Intermediate and University Students. By James J. O'Dea, M.A., formerly Professor of Mathematics, Natural Philosophy, and English Literature in St. Francis' College, Brooklyn, New York, and St. Jarlath's College, Tuam. Parts I. and II. Pp. x + 616, liv. (Longmans, Green, and Co., 1897, 1898.)

WHATEVER may be thought of the body of this work, there can be no doubt that the preface, at any rate, is remarkably explicit.

"The 'Explicit Algebra' is the result of the Author's earnest desire to facilitate, as much as possible, the labour of masters and students in this department of Mathematics, and to enable them to obtain the maximum results at the minimum expenditure of time and trouble."

Again,

"The Author has spared neither time, nor labour, nor expense in his effort to make the work every way worthy of the object for which it has been intended: namely, as a theoretical and practical text-book on Algebra for all grades of Intermediate Education, University Matriculation (Pass and Honours), and First, Second, and Third Class Teachers."

Finally, having doubtless observed that a certain proportion of reviewers derive the substance of their remarks from authors' prefaces, Mr. O'Dea thoughtfully provides us with a well-balanced appreciation of his treatise ready to our hand.

"The leading features of the 'Explicit Algebra' are fulness of detail, without being uselessly exhaustive; lucidity and conciseness of statement; brevity and neatness in the manipulation of examples, which are numerous and varied, together with copiousness and variety of exercises methodically arranged, while the disposition of the various portions of the work considered as a whole is in strict logical sequence."

In order that the reader may estimate for himself the justification of this modest prologue, we hasten to give a few illustrations.

Page 1, Definitions 3, 4, 5:

"The Symbols of Quantity are the letters a, b, c, d, v, w, x, y, z. These symbols are used to represent numbers."

"An Algebraic Quantity is one that is expressed in algebraic language, and is supposed to be known or unknown."

"A Known Quantity is that which contains a given number of units of the same kind, and is represented by the leading letters a, b, c, d."

Here is fulness of detail, without being needlessly exhaustive!

Page 12 (the last of three pages devoted to addition):

"N.B.—When dissimilar terms which are to be added have a common literal factor, which is called the Unit of Addition, this factor may be annexed to the algebraic sum of the others.

"Example 5. Determine the algebraic sum of

$2a - \sqrt{b} + c$, $3c - 4\sqrt{a} + b$, $3a + d - 2\sqrt{c}$, $m + n - 3\sqrt{a}$.

"Arrange thus:

$$\begin{array}{r}
2a - \sqrt{b} + c \\
-4\sqrt{a} + b + 3c \\
3a + d - 2\sqrt{c} \\
-3\sqrt{a} + m + n \\
\hline
(5\sqrt{a} - 7)\sqrt{a} + (\sqrt{b} - 1)\sqrt{b} + (2\sqrt{c} - 1)2\sqrt{c} + d + m + n."
\end{array}$$

Considering that "literal" and "factor" have not been explained, that nothing has been said about surds except a scrappy definition of the "Sign of Evolution" only intelligible to those who know what a root is, and that the student has actually been left to himself to find out that $2a$ is the product of 2 and a, this is a good sample of Mr. O'Dea's ideas of logical sequence. As another illustration, take the fact that the pupil has no opportunity of practising the use of symbolical language intelligently until he reaches problems on simple equations, p. 165.

The proportion of theory to practice (and such practice!) in this remarkable book is perhaps one to twenty, on a generous estimate. Here are tastes of the author's quality, when he digresses for a time into the barren wilds of theory.

"When an algebraic expression containing x is divided by $x - a$, the remainder is the same as that which results from substituting a for x in the original expression.

"Proof: Let the expression $ax^3 + bx^2 + cx + d$ be divided by $x - a$ until the remainder R, does not contain x, and let the quotient be represented by Q. We then have

$$\frac{ax^3 + bx^2 + cx + d}{x - a} = Q + R;$$

$$\text{"}\therefore ax^3 + bx^2 + cx + d = Q(x - a) + R.$$

"This relation holds for *all* values of x. Hence, since R does not contain x, it will undergo no change whatever value be assigned to x. Substituting a for x, therefore, we get

$$\begin{aligned} a^4 + a^2b + ac + d &= Q(a - a) + R \\ &= Q \times 0 + R = R. \end{aligned}$$

Thus,

$$R = a^4 + a^2b + ac + d.$$

This principle is called the Residual Theorem."

Observe here the charming vagueness of an "algebraic expression"; the ingenious substitution of R for $R/(x - a)$, which is not a misprint, because the same thing is done three times on a previous page; and lastly the use of the same symbol Q to represent two entirely different things, namely the original quotient, and its value when a is put for x.

Here is the "demonstration" of one case of the rule of signs in multiplication:—

$$\begin{aligned} \text{"} -a \times -b &= -a \times m \text{ (assuming } m = -b) \\ &= a \times -1 \times m = a \times -m \\ &= a \times -(-b) = a \times b = ab; \\ \therefore -a \times -b &= +ab.\text{"} \end{aligned}$$

The *petitio principii* in the second line would be hard to beat.

As might be expected, Mr. O'Dea's discussion of the theory of indices affords a magnificent display of his peculiar gifts of "conciseness, lucidity, logical sequence," and the rest of it. To give one instance, on p. 37 we have

$$\begin{aligned} \text{"}\frac{a^m}{a^n} &= \frac{a \times a \times a \ldots (a \text{ being taken } m \text{ times})}{a \times a \times a \ldots (a \text{ being taken } n \text{ times})} \\ &= a \times a \times a \ldots (a \text{ being taken } m - n \text{ times}) \\ &= a^{m-n}:\text{"} \end{aligned}$$

and this is immediately followed by

"Proposition IV.—The reciprocal of any quantity with a positive exponent is equal to the same quantity with an equal exponent taken negatively.

"Proof:

$$\frac{1}{x} = \frac{x}{x^2} = x^{1-2} = x^{-1}.$$

"So, too,

$$\frac{1}{x^3} = \frac{x^2}{x^5} = x^{2-5} = x^{-3},$$

and

$$\frac{1}{x^m} = \frac{x^n}{x^{m+n}} = x^{n-m-n} = x^{-m}.$$

"This is a very useful principle, and should be carefully attended to." This "proof" is repeated later on (p. 253), and the rest of the chapter on indices, so far as theory goes, is of a similar kind.

To give anything like a full account of the contents of this book, its utter absence of plan or proportion, its preposterous and antiquated arrangement, its shallow pretence of "theory," and its innumerable misleading and even erroneous statements, would take up too much space. It does not much matter where we look. "If one root of a quadratic equation be imaginary, the other will also be imaginary," nothing being said as to the reality of the coefficients; "now the greater the value of n, the smaller does r^n become. Hence (!), when n becomes indefinitely great, r^n will become indefinitely small." "Sum (1) to n terms, and (2) to infinity the series $1 + 3x + 5x^2 + 7x^3 + \ldots$," where neither in the question, nor in the solution, is any restriction imposed on the value of x. "Let x = circumference of fore-wheel," &c., concluding with "$x = \frac{504 - 156}{29} = 12$ feet." "Find the values of x, y and z from the simultaneous equations

$$x = a(y + z);\ y = b(z + x);\ z = c(x + y),$$

and prove that $ab + ac + bc + 2abc = 1$"; "the only four factors of 30 are 1, 2, 3, and 5,"—so much for its accuracy in detail. The primary definitions and the four fundamental rules are disposed of in fifty pages, "imaginary quantities" in ten, two of which are taken up by playing tricks with the complex cube roots of unity, while half a page goes to a misleading "demonstration" that $\sqrt{-a} \times \sqrt{-b} = -\sqrt{ab}$; fifty pages are occupied by chapters on indices, surds, and simple equations involving radicals, very inaccurate and choked by the usual fantastic examples; seventy pages are assigned to ratio, proportion, variation, and progressions: such is Mr. O'Dea's conception of the relative importance of the different items of his programme. "Elementary Factoring" (all jumbled up) will be found on pp. 57–73; quadratic equations are deferred until p. 319: logical sequence, forsooth, requires the precedence of Fractions, Involution, Evolution, Indices and Surds, and the substance is sacrificed to the shadow accordingly. Of graphical methods or illustrations there is not a trace: there is not a single geometrical figure in the book; the bearing of algebraical sign upon the "sense" of geometrical and physical quantities is absolutely ignored; and nothing is said about the nature or properties of logarithms. Not only is it possible for a clever boy to work through the whole of this book, and be as ignorant of the theory of algebra as when he began; he will be totally unacquainted with those elementary practical things which are most important for him if he wishes to apply his knowledge to engineering or to physics.

The book is avowedly written to help teachers to obtain "results": that is, to exploit their unhappy pupils for the purpose of scoring in examinations, and so getting grants, or scholarships or some other kind of profit. A method is recommended because it will impress an examiner more favourably, and earn a greater number of marks: the student's attention is directed to this or that, not because it is important in itself, but because the candidate is very likely to be asked a question about it; and an enormous amount of misplaced ingenuity is wasted upon the solution of ridiculous and fantastic questions which ought never to have been set.

It would not be fair to lay the whole blame for all this upon Mr. O'Dea. Like the poor Irish schoolboys, he is the victim of a most iniquitous system: that "payment by results" which warps and corrodes every branch of primary and intermediate education in Ireland. That this plan was originally adopted with the best intentions may be admitted; but it is a disgraceful scandal that it should be continued in Ireland, when it has been (reluctantly enough, it is true) abandoned in Great Britain. The evils of it have been exposed again and again; it has been denounced unanimously by all true teachers who have seen how it works; it puts a premium upon wrong methods, it encourages quackery and cruelty, it destroys sympathy between master and pupils, and the "results" which it produces are a delusion and a sham. It is heart-breaking to think of whole generations of clever, docile Irish lads condemned to the soul-destroying slavery which this rotten system perpetuates. And the evil is intensified when, as in the case of mathematics, the examinations for which the pupils are prepared are thoroughly unsatisfactory. Among the examples contained in this book are the following:—

(1) Simplify

$$\frac{b^2c^2}{(a-b)(a-c)} + \frac{c^2a^2}{(b-c)(b-a)} + \frac{a^2b^2}{(c-a)(c-b)}$$

(Preparatory Grade.)

(2) If $a = 9$, $b = 5$, $c = 2$, $d = 8$, find the value of

$$\frac{c}{\sqrt{a}} + \frac{1}{15}\left(\frac{b}{2}\right)^3 - \frac{3}{40}c^2 - 2\tfrac{1}{3}\sqrt[3]{\frac{1}{d^2} - \frac{ad}{bc^5}}$$

(Preparatory Grade.)

(3) Determine the value of

$$\{x^2 + (a+b)x + ab\}(x^3 + ax^2 + abx + a^2b) - (a^2 + x^2)(x - b)$$

when $x = -a$. (Junior Grade.)

(4) If $a + b + c = 0$, find the value of

$$\frac{b+c}{bc}(b^2 + c^2 - a^2) + \frac{c+a}{ca}(c^2 + a^2 - b^2) + \frac{a+b}{ab}(a^2 + b^2 - c^2)$$

(First Class Teachers.)

(5) If

$$x = \tfrac{1}{2}\left\{\left(\frac{a}{b}\right)^{\frac{1}{2}} - \left(\frac{b}{a}\right)^{\frac{1}{2}}\right\}$$

show that

$$\frac{2a(1 + x^2)^{\frac{1}{2}}}{x + (1 + x^2)^{\frac{1}{2}}} = a + b$$

(Middle Grade.)

(6) Show that the expression

$$\frac{(x+2)^{\frac{1}{2}}}{(x-2)^{\frac{1}{2}}}\left\{\frac{4}{(x^2 - 1)(x^2 - 4)^{\frac{1}{2}} + (x^2 - 3)x + 2} - 1\right\}$$

is equivalent to the fraction $\frac{1 + x}{1 - x}$ (Senior Grade.)

Of these (1) is far too hard for any preparatory grade; (2) is a fine derangement of symbols, wholly unlike anything that occurs in practice (properly so called); (3) is a miserable trap, presumably set for the purpose of inducing the candidates to waste half an hour in working out the products; in (4), if you guess that "the" value is 0, and are handy with your dodges, you will score heavily, otherwise ——!; (5) and (6) speak for themselves. Other examples, equally absurd, may be found by the dozen in the "Explicit Algebra"; in fact, if Mr. O'Dea has made a fair selection, it may be inferred that the Irish Government papers in algebra are occasionally very far from being suitable for the purposes for which they are supposed to be designed. How can teachers, working for a grant, be expected to teach algebra rationally, when the test that is applied to their pupils consists of a silly medley of questions, some threadbare and stereotyped, and others merely puzzling and artificial; while, with the exception, perhaps, of a couple of problems to be solved by equations, no attempt is made to gauge the candidate's reasoning powers?

Meanwhile My Lords the Commissioners of National Education in Ireland refuse to budge, in spite of the overwhelming verdict of competent opinion, nay in defiance of the unanimous protest of their own inspectors (see the *Manchester Guardian* for September 19, p. 7). No doubt their precious system works smoothly enough from their point of view; the papers are set on traditional lines, the marks obtained are neatly tabulated, and the grants and scholarships impartially distributed accordingly; how can any one, they may ask, reasonably object to such an obviously fair and practical procedure? And so the costly, wasteful, and inefficient machinery continues to grind; for all the world like a mill devised to scatter the flour and preserve the husk and bran.

G. B. M.

CLASSIFICATION OF THE VERTEBRATA.

Syllabus of Lectures on the Vertebrata. By Prof. E. D. Cope. Pp. xxxvi + 136. (Philadelphia: University of Pennsylvania, 1898.)

A Classification of Vertebrata, Recent and Extinct. By Dr. H. Gadow. Pp. xvii + 82. (London: Adam and Charles Black, 1898.)

An almost pathetic interest attaches to the former of these works, since it is the last scientific communication which Prof. Cope was able to make to the world, and was sent to press only a few days before his death. Its passage through the press was supervised by Prof. Osborn, who has added, by way of an introduction, an account of the life and works of the late Professor. The "Syllabus of Lectures," as it now appears, is a classification of the Vertebrata slightly expanded, and constitutes an elaboration of the scheme which Prof. Cope propounded some years ago in the *American Naturalist*.

The fertility which Prof. Cope has always exhibited for inventing new names is here seen to perfection, though it will probably be regarded with some consternation by the rising generation of students. Tables are given showing the stratigraphical range of the chief divisions, and the illustrations, though many of them crude, are a useful addition.

Ichthyologists who are conversant with Prof. Cope's works will not be surprised to find the Ostracoderms grouped with the Cyclostomes, but the definite inclusion of the Tinamous with the Ratite birds will find little support among ornithologists. Many of the expressions used are ambiguous, and even misleading. The urostyle of the Anura, being situated behind the sacral vertebra, cannot be formed of united *lumbosacral* vertebrae (p. 43), and the statements concerning the absence of median fins in Batrachia (p. 12), and the freedom of the palato-pterygoid arch in the Dipnoi (p. 17), require explanation.

The editing of the work, moreover, is not above criticism, *Serpentes* and *Ophidia* occurring indifferently, and on the same page, as the ordinal name of the snakes (p. 75). The oldest multituberculate mammals are said to occur in the "Trias of South Africa in the Karoo Beds," (p. 103)—evidently a tacit reference to *Tritilodon*—and yet Tritilodon is classed with the Gomphodont reptiles on page 65.

Dr. Gadow's book is more likely to find favour with European students, the names given to the groups being more familiar. The convenience of the reader is studied by leaving the left-hand pages blank for annotations. The geological range of the extinct forms, and the geographical distribution of the recent ones are given; and the glossary, showing the derivation of most of the Latin and Greek names, is both useful and accurate.

Dr. Gadow appears to be chary of accepting taxonomic innovations, yet loath to ignore them, and the result is not unfrequently incongruous. He does not support Cope so far as to place the Ostracoderms with the Cyclostomes, but creates for them a new and unnecessary super-class, the "Hypostomata" (p. 4), equal in value to, and intermediate between, the Cyclostomes and the Gnathostomes. And again, while not bold enough to follow Hubrecht in including *Tarsius* with the apes, he yet goes so far as to give it a sub-order all to itself (p. 53).

The diagnoses are not always full enough to be effective (that of the Prosauria, p. 17, not excluding the Geckoes); and even the most elementary student of zoology will object to the statement (p. 43) that the tibia and fibula are separate in the rabbit.

The book, however, in spite of some blemishes, will prove a useful addition to the student's library.

OUR BOOK SHELF.

First Principles of Electricity and Magnetism. By C. H. W. Biggs. Pp. 481 + xv. (London: Biggs and Co.)

This book is intended, it is stated in the author's preface, for beginners in practical work, and is an expansion of a series of papers which appeared in the *Electrical Engineer*. The author considers it necessary to lead off with a chapter on atoms, molecules, mass, force, weight (and the fundamental units), work and energy. The idea evidently is to convey to the beginner information in a more or less familiar and chatty style, and the book is certainly readable. We wish we could say that the information was always quite correct. As containing examples of well-meant but inaccurate statements, we may refer to the explanation (?) of the different gravit-

ational attractions in the same mass at different points of the earth's surface. The account of the effect of the flattening at the poles leaves much to be desired, and the effect of centrifugal force is not even mentioned.

Again, on p. 21 we have "unit acceleration as in scientific calculations, usually 1 centimetre per second. In many practical calculations it is 1 foot per second." Whatever may figure in practical calculations, it is certain that neither of these is scientifically an acceleration at all. Also, though we have no wish to be hypercritical, there is something quaint about the equation

"$150 \times 25 = 3750$ poundals."

When Mr. Biggs comes to electrical matters he is happier. His descriptions of hydrostatic analogies may help some readers, *e.g.* the inquiring town councillor, to form an idea of "electrical pressure," though we fear the notion may linger that it is really a kind of pressure.

But when he gets to Ohm's Law, Mr. Biggs says, after arriving at the result $C \propto E/R$, "In the early part of this century, Prof. Ohm proved more than this with steady continuous currents, not only that $C \propto E/R$, but that $C = E/R$, or expressed numerically in practical units, amperes $= \frac{\text{volts}}{\text{ohms}}$." How Prof. Ohm "proved" this Mr. Biggs has not divulged, and it would be interesting to know. We had thought, innocently, that the *equality* of C to E/R was an affair of choice of units, and not of proof at all.

The cuts in the book are numerous, but, except a few here and there, are badly printed. The figure, on p. 185, of a long thin gentleman (in a rather modern dress) extended along a rod inside what looks like a stone coffin several sizes too big for him, at first sight startled us. Underneath, in black type, was the legend, "A Stretch of the Imagination"! but this, we found, referred to the following paragraph, which, curiously enough, deals with elastic threads.

The latter and really practical part of Mr. Biggs' book may be of service to some readers. It contains a good deal of useful information, conveyed in Mr. Biggs' genial, if a little conscious, style. But we should counsel a really earnest student, and especially a beginner, to choose a text-book in which a more serious attempt is made to grapple with the real difficulties of the subject.

Medical Diseases of Infancy and Childhood. By Dawson Williams, M.D., F.R.C.P. (Lond.), Physician to the East London Hospital for Children, Shadwell. Pp. xiv + 634. Plates 18; figures 18. (London: Cassell and Co., Ltd., 1898.)

THE book before us, which is correctly described by the author as a handbook, is intended "to act as a guide to clinical study" to young practitioners of medicine, and those who have not previously paid much attention to the subject. After introductory chapters treating of growth, clinical examination and food, the author proceeds to consider the individual diseases of children, and to indicate how the pathological processes, and their accompanying clinical phenomena, are different in children and adults. It would, of course, be impossible in a short notice like the present to give an account of the varied and practical information contained in Dr. Williams's book. Under the heading of diphtheria, the results of the antitoxin treatment, as culled from the statistics of the Metropolitan Asylums Board and the American Pediatric Society, are given, the author rightly observing that the statistical figures are actually less favourable than the reality. The interesting subject of the effect of the antitoxin treatment upon the complications of diphtheria, so often of such importance in children, is also discussed. Cretinism and its treatment by administration of the thyroid gland is considered. Hepatic disease in children, often a subject of considerable difficulty to the practitioner, is well treated. A list of prescriptions, a few invalid cooking receipts, and a good index conclude the volume. The book will unquestionably be of use to the general practitioner and the student, and, while not capable of replacing the larger text-books on the diseases of children, will form a most valuable supplement to the various treatises on general medicine. F. W. T.

A Text-book of General Botany. By Carlton C. Curtis, A.M., Ph.D., Tutor in Botany in Columbia University. Pp. viii + 359. (New York, London, and Bombay: Longmans, Green, and Co., 1897.)

DR. CURTIS has added another to the existing long list of intermediate botanical text-books. His book is readable, and on the whole a fairly good one, and the number of new illustrations it contains at once impress the reader in its favour. Opening with a general account of anatomy, he devotes the second chapter to physiology. But the great bulk of the book (p. 87–340) is given up to systematic and morphological matters. A very short sketch of palæobotany, together with an index, conclude the work. The general treatment is based on the type system, and Dr. Curtis has done well in showing how this much abused method lends itself in reality very well to a connected exposition of the taxonomic parts of botany. Unfortunately, perhaps inevitably, the text is rather scrappy in many places, although this is partly atoned for by the fulness of the many laboratory exercises which are distributed through the book.

We have noticed a rather considerable number of misprints scattered through the pages; these will doubtless disappear in a future edition, which is almost sure to be called for, since the book, if used as an adjunct to the laboratory in the sense intended by its author, supplies a distinctly felt need for a guide suitable for intermediate students.

Domestic Hygiene. By Arnold W. Williams, M.B. C.M. (Edin.), D.P.H. (Lond.). Pp. 175. (London: George Bell and Sons, 1898.)

The Teacher's Manual of Object Lessons in Domestic Economy. Vol. ii. By Vincent T. Murché. Pp. viii + 334. (London: Macmillan and Co., Ltd., 1898.)

Lessons in Domestic Science. Part ii. By Ethel R. Lush. Pp. 77. (London: Macmillan and Co., Ltd., 1898.)

THESE three volumes all deal worthily with matters included in the science of health, and they will all assist in extending a knowledge of the laws of life. Dr. Williams's manual contains the substance of lectures delivered by the author at many rural and urban districts on the causes and prevention of disease and co-related subjects affecting the public health. The book will be found of service to technical instruction classes and others of a similar kind.

Mr. Murché's book is "adapted to meet the requirements of the Education Department in the Class Subject of Domestic Economy as laid down in the Code for 1898." It contains notes and hints for teachers who have to teach domestic economy to Standards III. and IV. of public elementary schools. In the former standard, the children are expected to know something of the materials used in clothing and the materials used in washing; in the latter standard, they are taught simple facts concerning the use and sources of food, the hygiene of clothes, and laundry-work. Mr. Murché's books have all been received by favour with teachers engaged in elementary schools, and the present volume will doubtless have the same welcome extended to it.

Domestic science is a new subject recently adopted by the Education Department. It differs from domestic economy in the fact that principles rather than processes are dealt with. The parts of the subject included in Miss Lush's booklet refer to the functions and preparation of food, and the dwelling. A course such as it provides educates as well as interests the pupils.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of the Aurora Spectrum.

IN your issue of June 16, Prof. Schuster calls attention to the fact that the wave-length of the aurora line nearly coincides with the wave-length of the bright green line in the spectrum of krypton. Prof. Ramsay and Dr. Travers give the wave-length of this line as 5566·3. I find it to be 5570·40 (Rowland's scale), which brings the line close to the mean of the best determinations of the aurora line. According to Scheiner ("Die Spectralanalyse der Gestirne") the best measures, when reduced to Rowland's scale, are :—

Angström ...	5568	Huggins ..	5572
Vogel	5572	Copeland ...	5573
Vijkander ...	5573	Gyllenskiöld	5569
Lemström ...	5570		

Mean 5571·0.

To this must be added Campbell's determination at Mount Hamilton: 5571·6 (see translation of Scheiner's "Sp. d. Gest." by E. Frost, p. 326).

Considering the difficulty of measuring the aurora line, I think the difference is not too large to be compatible with the identity of the lines. Satisfactory evidence might be gained, if the other krypton lines could be observed in the spectrum of the aurora. I subjoin the mean of four different determinations of the yellow and green krypton lines. They were photographed on orthochromatic plates, together with lines of mercury, sodium and argon, which served as standards.

	Mean error.	Ramsay and Travers.
5562·35	0·03	5557·3
5570·40	0·03	5566·3

Hannover, Technische Hochschule, November 2. C. RUNGE.

The Boring at Funafuti.

FURTHER information has been received this week from Prof. David, of Sydney, as to the progress of the boring at Funafuti. On September 6 it had reached a depth of 987 feet, passing through a hard dolomite-like coral rock, apparently similar to that mentioned previously as occurring below about 700 feet. Boring in the bed of the lagoon from the deck of H.M.S. *Porpoise* had been continued; the one mentioned in your last number was carried through sand, composed of fragments of calcareous organisms in which broken pieces of coral became commoner in descending, to a depth of 144 feet in the bed-rock of the lagoon, or in all 245 feet below sea-level. There progress was stopped by hard coral rock, which could not be pierced, because the great length of unsupported pipe (about 120 feet) made driving impossible, and the loose stuff above prevented them from applying another device. Captain Sturdee, though unable to stay much longer at the island, contrived to move the *Porpoise* about 90 feet nearer to the centre of the lagoon, where another boring was made at about the same depth. This was carried through 80 feet of sand, as before, which was then succeeded by a rather hard coral gravel; the lumps varying up to the size of a man's fist. It was pierced to a depth of 33 feet, when the time limit was reached, and the work was necessarily abandoned. The results, however, are most interesting, and our friends in Sydney may be congratulated on the success of boring so far in a depth of a hundred feet of water. When letters left the island the main bore was still progressing, though the supply of diamonds was nearly exhausted, so that there seems every hope that it will be carried below a thousand feet. But what has been already accomplished will be an immense addition to our knowledge of atolls.

T. G. BONNEY,
Vice-Chairman of the Coral Reef Committee of the Royal Society.

Asymmetry and Vitalism.

It seems to me that Prof. Japp has not understood the purpose of my reference to "the formation of hematite nodules and flints in chalk." I instanced this simply as showing that segregation slowly takes place notwithstanding great restraints, such as that which a chalk-stratum offers; and my argument was that if segregations of hematite and flint take place in long periods notwithstanding such great restraints, it may reasonably be inferred that segregations of such slightly-different molecules as those of dextro- and laevo-protein would gradually take place under the slight restraints offered by a colloidal substance like protein. Unless due time is given, nothing can be expected.

Prof. Japp thinks I do not "quite realise to what extent enantiomorphous molecules are alike." He says that the two classes of molecules differ only as right and left hands differ. That seems to me a sufficient difference to determine segregation. There must be different *attitudes* in relation to incident forces. Can it be held that differences of attitude have no effects? The members of a mixed mass of molecules differing in their attitudes could not react in absolutely the same manner upon incident forces; and it may be inferred that their differential reactions will produce differential motions.

But Prof. Japp's fundamental fact seems to me to furnish an answer to his criticism. The basis of his argument is that these groups of right-handed and left-handed molecules severally produce rotation of a polarised ray in different directions. If they thus act differently upon the ray when they form an aggregate, they must act differently upon it when existing individually. Though in a mixed aggregate their respective actions on the ray cancel one another, yet each molecule of either kind will be acted upon and will react differently from each molecule of the other kind, and their reactions will *not* cancel one another. Hence there will be initiated those differences in their behaviour which cause segregation. If in a state of nature they are under some conditions subject to polarised rays, the implication seems to be that this result will take place. HERBERT SPENCER.

Brighton, October 29.

I DO not understand how Mr. Herbert Spencer can imagine that the action of plane-polarised light (a form of energy which is merely polar—not asymmetric) can possibly effect the separation of enantimorphs. As I pointed out in my former letter, nothing short of an asymmetric influence could do this.

Speaking of enantiomorphous molecules, Mr. Spencer says: "There must be different *attitudes* in relation to incident forces. Can it be held that differences of attitude have no effects?"

There will undoubtedly be differences in the effects; but, owing to a peculiarity in the behaviour of enantiomorphs under the influence of symmetric forces, these differences will not be apparent in the final result. Thus, if we subject dextro-tartaric acid and laevo-tartaric acid separately to the action of heat, both will decompose at the same temperature and at the same rate, and will yield the same products in the same relative amounts. There is a "difference of attitude," and there will be a difference in the "effects," so far as in the one case some of the right-handed acid becomes left-handed, whilst in the other, some of the left-handed acid becomes right-handed; and in both cases, by similar inverse changes, stopping short, however, half-way, some mesotartaric acid is formed. But in both cases the final result is the same: namely, the establishing of an equilibrium represented by an optically inactive mixture of racemic acid with a little mesotartaric acid. There is a difference in the two *changes*—a difference which our knowledge of the opposite asymmetry of the two initial compounds enables us to read into the processes, thus saving Mr. Spencer's general proposition; but there is no difference in the *results*. But it is quite evident, from what Mr. Spencer has written about the separation of enantiomorphs, that it is in the results that he expects to find a difference; and here he will be disappointed, so long as symmetric influences only are brought to bear on enantiomorphs. Under such influences, just as in the foregoing case, *there occur two changes of inverse character, conditioned by, and exactly balancing, the inverse character of the two enantiomorphs, so that the final result is the same for both enantiomorphs.* This is what Mr. Spencer overlooks. He does not perceive that a uniform force acting upon two enantiomorphs may be modified by them so as to act in two opposite asymmetric modes. He must interpret his third "abstract proposition" and its corollary

(NATURE, vol. lviii. p. 592, col. 2) so as to include these special cases.

Similar considerations would apply to the action of polarised light on a mixture of enantiomorphs. The most that could occur would be the production of an equal rotation of enantiomorphous molecules in opposite senses, corresponding with their opposite asymmetry. That would not cause separation.

Again, take Mr. Spencer's first "abstract proposition" (*loc. cit.*), which runs: "Like units subject to a uniform force capable of producing motion in them, will be moved to like degrees in the same direction." How does he reconcile this statement with the fact that enantiomorphs have the same heat of formation: *i.e.* that the same atoms are moved by the same amounts of energy, not in the same direction, but in directions of opposite asymmetry, so as to form two asymmetrically distinct compounds?

I probably do Mr. Spencer no injustice if I assume that in 1862, when he formulated these "abstract propositions," he was not acquainted with the theory of molecular asymmetry, which at that time was not generally current, even among professed chemists. And if I might do so without offence, I would suggest that he should read the portion of Van 't Hoff's "Arrangement of Atoms in Space" (second edition) dealing with the question of molecular asymmetry, especially the section which describes the character of the isomerism due to the asymmetric carbon atom. He may then be able to recast his "abstract propositions" so as to include, at least more explicitly, the formation and behaviour of enantiomorphous molecules under symmetric influences F. R. JAPP.

The University, Aberdeen, November 2.

I AM not sure that much is to be gained by continuing this discussion further, but perhaps I may be permitted to add something to my first criticism of Prof. Japp's standpoint in view of his communication in last week's NATURE.

The statement of Prof. Japp's, which I specially criticised, was the following (where I italicise the words to which I wish to draw particular attention):—But the *chance* synthesis of the simplest optically active compound from inorganic materials is *absolutely inconceivable.*

To this I replied and still reply, it is *not* absolutely inconceivable. An optically active compound means merely a preponderance of one kind of enantiomorph, and *chance* will always produce this, given enough trials and length of time to make them. Prof. Japp twits me with the ineffectiveness of twenty molecules, but I spoke not of twenty molecules, but of twenty coins, in order to bring home to Prof. Japp what a deviation from the average in the theory of chance really means. The probability of a deviation of 5000 in 1,000,000 molecules is easily calculated, and such a deviation is quite "conceivable," even if it be very infrequent. A deviation of 5000 in 1,000,000 molecules would give an optically active solution, whether sufficiently intense to be observed by the means at our disposal is another question. The statement that on the theory of *chance*, an optically active compound is *absolutely inconceivable* is, I take it, absurd. It may be very *improbable*, but this is not the term used by Prof. Japp.

Prof. Japp writes in his letter: "Prof. Pearson's twenty non-living asymmetrical molecules formed by the chance play of mechanical forces, would, so far as experiment informs us—although I freely admit that mere negative results are not conclusive—have no more influence on the asymmetry of other molecules formed in their neighbourhood than one toss of a coin has upon another toss." I reply that I think experiment shows they *have*. It is possible in Jungfleisch's process to get crystals which are purely right- or left-handed up to the size, say, of half an inch, sufficiently large for picking out. Now I take it that it is chance which produces a slight majority of one type of enantiomorphs at one or other point, and what I have termed "breeding," which encourages the collection of that type at the given centre until we get crystals purely right- or left-handed up to a size of half an inch. That a number of molecules of one kind, such as are required for these crystals, should be frequently formed, is totally opposed to the theory of *chance*, but I take it that a slight chance preponderance sets the "breeding" going.

Take a dish of such crystals and throw them out at random, and they scatter in all directions; one such crystal coming into a few drops of fluid forms an optically active medium consisting of enantiomorphs of one kind only. Thus even a total disappearance of one kind of enantiomorphs is not impossible, or "absolutely inconceivable" on the theory of *chance*. Prof. Japp speaks of the "vague and elastic" way in which I speak of the "breeding" process—I notice that Prof. Errera also uses the phrase "asymmetry begets asymmetry as life begets life." Let us confine the term then, for the present, simply to the process (of which so far the mechanism is unintelligible) by which chance having given a slight local preponderance of one type of enantiomorph, a group of the same type, visible and touchable, is formed there. It is perfectly conceivable that this is only a visible representation of the process by which living asymmetry selects its like, even in a non-crystalline compound. It is only the mechanism which is vague, not the fact.

Prof. Japp really complains in his address that an "eminent physicist" should say that an explanation of rotatory polarisation is still wanting. It is still wanting, because no *kinetic* theory, which is what a physicist requires, can be provided by what is after all only a geometrical *schema* of the chemist. Prof. Japp now writes that every chemist recognises that it is only a geometrical hypothesis, and he did not think so obvious a qualification needed statement to an audience of chemists. Then why, I ask, should Prof. Japp go out of his way to say that the theory was unknown outside the circle of organic chemists, and cite the "eminent physicist" as an example of such ignorance?

The fact is, that the moment we look at Prof. Japp's tetrahedron atoms, Figs. 1 and 2 of his paper, as *dynamical* systems, the right-handed and left-handed molecules do not respond in the same manner to symmetrical forces. The atoms not being identical, the centroid will not necessarily be the centroid of the tetrahedron; say, it is somewhat nearer to Z′ than H. Now whirl a thin cylindrical sheet of optically inactive mixture round the axis of the sheet, left- or right-handed rotation is indifferent; the left-handed tetrahedra will not be in *stable* equilibrium relatively to the centroid of the molecule in the same position as the right-handed. Consequently the former will all set, say, their X′ angle inwards, and the latter outwards; or at least some similar like difference of positions will differentiate like from unlike enantiomorphs. Now let a strip of the cylindrical surface be placed horizontally and allowed to fall, say, through a viscous fluid, the resistance to a tetrahedron going X′ foremost, may well be greater or less than one going HZ′Y′ foremost, and if so the left-handed molecules will be separated ultimately from the right. All this is purely hypothetical, but I introduce it because Prof. Japp asserts that it is "impossible" for any mechanical (symmetrical) forces to constantly select one of two opposite forms. I reply that the impossible is conceivable, if he will treat his molecules not as geometrical *schemas*, but as dynamical systems.

One last word. Prof. Japp refers in his address to a "vital force" which does not disobey the law of energy, but is purely *directive* of motion. I have seen such an idea several times mooted. The question is not, however, if something called vital force obeys the law of the conservation of energy, for the principle of energy *never* fully defined any motion, something else is also directly or tacitly assumed. In itself it only leads to *one* equation, not sufficient to describe any motion. The problem is whether "vital force" obeys *all* the laws of motion—for example the conservation of momentum, angular and linear, which it could hardly do if it changed the direction of motion. I am quite unable to realise why some chemists and physicists seem to think a disregard for the conservation of momentum less miraculous than a disregard for the conservation of energy. I do not see why the less important principle should be made more of a fetish than the wider reaching principle. If "vital force" does obey all the laws of motion, then it can only be a rather bad name for some piece of mechanism, to which the most ardent supporter of a mechanical theory of the universe (such as Buchner or Moleschott, not I) could not possibly object. KARL PEARSON.

University College.

WHILST Prof. Japp is to some extent justified in saying that all his critics "seem to be moving in that unreal world where a fount of type, if jumbled together sufficiently often, ends by setting up the text of *Hamlet*," still it must be borne in mind that he himself provoked a discussion in such an imaginary region by raising the question as to the possibility of producing, without the interference of a living agency, an optically active

substance unaccompanied by its enantiomorph. The possibility of such an occurrence has been pointed out by Profs Karl Pearson and Fitzgerald, and is of course open to no doubt. Indeed, to use Dr. Japp's own simile, it must be conceded that if the type were jumbled an infinite number of times, it would lead not only once but an infinite number of times also to the text of *Hamlet* being set up! In the matter of the synthesis of asymmetric molecules throughout the past history of the earth we are, it is true, not dealing with an infinite number of events, but still with a number of an extremely high order, and in the course of this enormously long series of events such an exceptional occurrence as the exclusive production of a considerable aggregation of similarly asymmetric molecules may have taken place. This Prof. Japp himself appears to recognise, but he does not admit that such an aggregation of asymmetric molecules can by "breeding" add to the number of asymmetric molecules which are unaccompanied by their enantiomorphs, and he has disposed of the vague suggestions of such breeding advanced by his critics. He appears to me, however, to have overlooked one possible way in which such breeding can occur. If we take an asymmetric molecule containing for simplicity a single asymmetric carbon atom, and by purely chemical synthesis generate a second asymmetric carbon atom in the molecule, the new carbon atom may, as we know from the researches of Emil Fischer, always have the same asymmetry, to the exclusion of its enantiomorphous arrangement. But these asymmetric molecules containing two asymmetric carbon atoms might by purely chemical processes be broken down so that each yielded two molecules containing an asymmetric carbon atom apiece. Each of these two resulting molecules with their single asymmetric carbon atom would now be ready to go through a similar cycle of changes which would result in four molecules, each containing a single asymmetric carbon atom, and so on. In this manner an indefinitely large number of asymmetric molecules, unaccompanied by their enantiomorphs, might be bred from a single one without the interference of any asymmetric agency, living or otherwise.

It appears to me also quite possible that the asymmetry of solar radiation may originally have determined the exclusive synthesis of one enantiomorph, and that the latter was in some way or other utilised in the evolution of the first organism, by which then this particular enantiomorphism was further transmitted indefinitely. This is an entirely different idea from that which led Pasteur to try his celebrated but abortive experiments on plants in the hope that by reversing the asymmetry of the sun he would obtain the vegetable asymmetric products of the reverse sign to that which they normally possess. When Pasteur became a biologist as well as a chemist, he rapidly realised that the asymmetric influences present in the germ of life itself far outweigh the asymmetric influence of solar radiation in determining the formation of one enantiomorph to the exclusion of its fellow. It has indeed always appeared to me highly remarkable that Pasteur should have embarked on these particular experiments at all, inasmuch as the negative answer to his inquiry is already given by nature; for, as Prof. Japp points out, the asymmetry of solar radiation in the northern is the reverse of that in the southern hemisphere, whilst the asymmetric vegetable products in both hemispheres are identical and not enantiomorphous. The November Meteors.

PROF. J. COUCH ADAMS, in his classical investigation into the dynamics of the great Leonid swarm, employed Gauss's method in determining the perturbations of the surrounding planets upon these meteors. Gauss's method furnishes the average amount of each perturbation, and although this was sufficient for the immediate object which Prof. Adams had in view, it has appeared desirable to penetrate more deeply into the problem.

With this end in view the actual perturbations during the 33¼ years of the present revolution are being computed under the direction of Dr. Downing, F.R.S., the Superintendent of the Nautical Almanac, the calculations being made for meteors occupying a definite position in the stream, viz. that through which the earth passed in 1866. This computation will be completed within the next few days; and as the result, so far as the motion of the node is concerned, can be made the basis of an attempt to forecast the times of the greater showers—one of which may possibly present itself next week—it seems desirable that this use shall be made of the work which is being done.

The greater Leonid showers are occasioned by the earth passing through the stream of ortho-Leonids, *i.e.* those numerous Leonids which revolve round the sun in nearly identical elliptic orbits. There are other Leonids moving in orbits that sensibly differ from the ortho-orbit, and these may be called clino-Leonids. Some of the clino-Leonids encounter the earth in rather scattered formation every year, but the ortho-Leonids are a dense procession of meteors advancing along nearly coincident paths and occupying only a portion of the orbit at any one time.

It is just possible that the front of this procession may extend far enough forward for the earth to encounter it this year, and we are almost certain to pass through the stream in the Novembers of next year and of one or two of the following years. On each such occasion the earth receives a downpour of meteors which lasts for so few hours that those observers only who are fortunate enough to be on the advancing side of the earth can witness the marvellous display.

If there is one of these greater showers this year; if the meteors that shall constitute it traverse the same orbit as did those that the earth encountered in 1866; and if the advance of the node since 1866 were the same as that assigned by Gauss's method: then would the middle of the shower of this year occur at the time

1898 November 14d. 5h.

But the computation which is being made under Dr. Downing's direction shows unmistakably that the last of these conditions has not been fulfilled, that on the contrary the perturbations during this revolution, especially those arising from Jupiter and Saturn, have been far above the average.

Now all the calculations which have been made refer to meteors situated at what we may call Station A in the procession, by which is meant that part of the stream through which the earth passed in 1866. This part of the stream will not return to the node—the point of intersection between the meteoric orbit and the earth's orbit—till the end of January 1900. Accordingly Station B, which the earth will encounter this year, is situated in the procession about a year and a quarter in advance of Station A.

The relative positions of the disturbing planets and the meteors make it almost certain that meteors B have suffered perturbations during the current revolution, which sensibly differ from those affecting meteors A; but the difference is probably not very large. Again, they may have started along slightly different orbits. And, thirdly, Adams's orbit can only be relied on as approximate, since it is based on an insufficient determination of the radiant.

On these accounts there is risk of error in applying to meteors B, the results obtained in the case of meteors A.

With these reservations we may venture to make the correction; and accordingly it is intended as soon as the computer's work is sufficiently advanced, to send to the daily papers (since NATURE will be published too late) an announcement of the amount of the correction found in the case of meteors A. It will probably correspond to an epoch, several hours, possibly more than a whole day, later than that calculated on the average shift of the node.

If when the correction is published it is applied to the date given above, viz. to 1898 November 14d. 5h. (5 o'clock in the afternoon of Monday the 14th instant), it will furnish the best attempt which the data at our disposal seem to permit, to assign the time of the great shower if such an event occurs this year. It will be understood that this can only be offered as a prediction with the important reservations enumerated above.

Everything as yet known seems to betoken that the true time will prove to be many hours later than 5 o'clock on Monday afternoon, so that if one of the great meteoric showers reaches the earth this year it may perhaps happen on Monday night after half-past ten, or on Tuesday night after the same hour, in either of which events it will be visible from all stations on this side of the earth where the sky is not clouded.

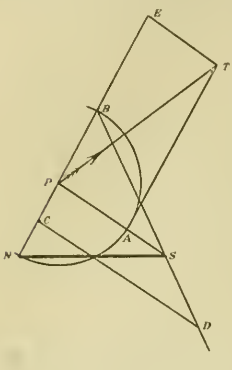
Construction for the Direction of a Magnetic Line of Force.

In Prof. Gray's review of Riecke's *Lehrbuch*, a construction for the direction of the line of force at any point, due to a short magnet, is given.

If the magnet be long, then the following construction holds:

Let N and S be the two ends of the magnet and P the point, nearer, say, to N than to S. Take A in PS and B in NP produced, so that PA = PB = PN. Take C in BN, so that BC measured towards N equals PS. Draw CD parallel to PS, D being in the line BS. Measure PE away from N, so that PE = CD. The diagonal PT of the parallelogram AE is the direction required.



J. H. Vincent.

Cavendish Laboratory, Cambridge.

The determination of the direction of the resultant force, at any point, due to a long, thin magnet, is of some importance as a laboratory exercise, and it is necessary to be able to compare the direction which a small needle takes up in its field with the theoretical direction. For such an exercise the bar should be a long, thin magnet as nearly uniformly magnetised as possible. For this case Mr. Vincent's construction gives the theoretical direction very neatly.

The direction may also be found by dividing the line NS externally, at a point R, say, in the triplicate ratio of NP to SP. The line joining R to P is the direction sought. This construction can be made with only a parallel ruler.

My friend Mr. G. B. Mathews has pointed out to me that this construction may be very conveniently used to draw the whole family of curves. For describe a circle through P dividing NS internally and externally in the ratio of NP to SP. The lines joining any point on this circle with N and S are in this ratio. Hence the direction of the force at each point of the circle is the line joining it with R. Thus, by a succession of circles and corresponding positions of R, the whole series of curves can be laid down.

The following method is perhaps not so good, but is also very easy to remember. A diagram is not necessary. Describe a circle touching the line NP at N, and cutting the line SP produced beyond P in the points H, K, of which H is the nearer to P. From P towards N lay off a distance PL equal to PH, and through L draw a circle touching SP at S and cutting PN, produced, if necessary, in M. The diagonal passing through P of the parallelogram described on PK, PM as adjacent sides is in the direction of the line of force at P.

When either of the angles SNP, NSP is very obtuse, the last construction should be carried out by drawing the circles so as to give equal segments PH, PL both lying on the side of P towards NS. Then a distance PK′ = PK can be laid off along SP produced, and the parallelogram described on PK′, PM as adjacent sides. There are probably a great many ways of solving this problem: I have hit upon three other distinct methods, which I will not take up space with describing here. I may mention also that I have given a simple method of laying down successive points on a line of force in my "Magnetism and Electricity," vol. i. p. 14, figs. 12 and 13.

The construction for the direction of the force due to a short magnet, described in my review of Prof. Riecke's book, was given by Hansteen ("Magnetismus der Erde," s. 208), and again by Gauss ("Vorschriften," &c., Werke Bd. 5, s. 435). It is to be found in Prof. Chrystal's article on "Magnetism" in the "Encyclopaedia Britannica," and in my treatise on "Absolute Measurements," vol. ii.

A. Gray.

THE CHEMISTRY OF THE STARS.[1]

When, on returning from India, I found that you had during my absence done me the honour of unanimously electing me your President, I began to cast about for a subject on which to address you. Curiously enough, shortly afterwards an official inquiry compelled me to make myself acquainted with the early doings of the Royal Commission of the Exhibition of 1851, on which I have lately been elected to serve, and in my reading I found a full account of the establishment of your Institute; of the laying of the foundation-stone by the late Prince Consort in 1855, and of his memorable speech on that occasion. Here, I thought, was my subject; and when I heard that the admirable work done by this and other local institutions had determined the inhabitants of this important city and neighbourhood to crown the edifice by the foundation of a University, I thought the matter settled.

This idea, however, was nipped in the bud by a letter which informed me that the hope had been expressed that I should refer to some branch of astronomical work. I yielded at once, and because I felt that I might thus be able to show cause why the making of knowledge should occupy a large place in your new University, and thus distinguish it from other Universities more or less decadent.

The importance of practical work, the educational value of the seeking after truth by experiment and observation on the part of even young students, are now generally recognised. That battle has been fought and won. But there is a tendency in the official direction of seats of learning to consider what is known to be useful, because it is used, in the first place. The fact that the unknown, that is the unstudied, is the mine from which all scientific knowledge with its million applications has been won is too often forgotten.

Bacon, who was the first to point out the importance of experiment in the physical sciences, and who predicted the applications to which I have referred, warns us that "lucifera experimenta non fructifera quaerenda": and surely we should highly prize those results which enlarge the domain of human thought and help us to understand the mechanism of the wonderful universe in which our lot is cast, as well as those which add to the comfort and the convenience of our lives.

It would be also easy to show by many instances how researches, considered ideally useless at the time they were made, have been the origin of the most tremendous applications. One instance suffices. Faraday's trifling with wires and magnets has already landed us in one of the greatest revolutions which civilisation has witnessed; and where the triumphs of electrical science will stop, no man can say.

This is a case in which the useless has been rapidly sublimed into utility so far as our material wants are concerned.

I propose to bring to your notice another "useless" observation suggesting a line of inquiry which I believe sooner or later is destined profoundly to influence human thought along many lines.

Fraunhofer at the beginning of this century examined sunlight and starlight through a prism. He found that the light received from the sun differed from that of the stars. So useless did his work appear that we had to wait for half a century till any considerable advance was made. It was found at last that the strange "lines" seen and named by Fraunhofer were precious indications of the chemical substances present in worlds immeasurably remote. We had, after half a century's neglect, the foundation of solar and stellar chemistry, an advance in knowledge equalling any other in its importance.

[1] An inaugural address delivered at the Birmingham and Midland Institute on October 25, by Sir Norman Lockyer, K.C.B., F.R.S., President.

In dealing with my subject, I shall first refer to the work which has been done in more recent years with regard to this chemical conditioning of the atmospheres of stars, and afterwards very briefly show how this work carries us into still other new and wider fields of thought.

The first important matter which lies on the surface of such a general inquiry as this is that if we deal with the chemical elements as judged by the lines in their spectra, we know for certain of the existence of oxygen, of nitrogen, of argon, representing one class of gases, in no celestial body whatever; whereas, representing other gases, we have a tremendous demonstration of the existence of all the known lines of hydrogen and helium.

We see then that the celestial sorting out of gases is quite different from the terrestrial one.

Taking the substances classed by the chemist as non-metals, we find carbon and silicium—I prefer, on account of its stellar behaviour, to call it silicium, though it is old-fashioned—present in celestial phenomena; we have evidence of this in the fact that we have a considerable development of carbon in some stars and an indication of silicium in others. But these are the only non-metals observed. Now with regard to the metallic substances which we find, we deal chiefly with calcium, strontium, iron and magnesium; others are not absolutely absent, but their percentage quantity is so small that they are negligible in a general statement.

Now do these chemical elements exist indiscriminately in all the celestial bodies, so that practically, from a chemical point of view, the bodies appear to us of similar chemical constitution? No, it is not so.

From the spectra of those stars which resemble the sun, in that they consist of an interior nucleus surrounded by an atmosphere which absorbs the light of the nucleus, and which therefore we study by means of this absorption; it is to be gathered that the atmospheres of some stars are chiefly gaseous, *i.e.* consisting of elements we recognise as gases here, of others chiefly metallic, of others again mainly composed of carbon or compounds of carbon.

Here then we have spectroscopically revealed the fact that there is considerable variation in the chemical constituents which build up the stellar atmospheres.

This, though a general, is still an isolated statement. Can we connect it with another? One of the laws formulated by Kirchhoff in the infancy of spectroscopic inquiry has to do with the kind of radiation given out by bodies at different temperatures. A poker placed in a fire first becomes *red*, and as it gets hotter, *white*, hot. Examined in a spectroscope we find that the red condition comes from the *absence* of blue light; that the white condition comes from the gradual addition of blue as the temperature increases.

The law affirms that the hotter a mass of matter is the further its spectrum extends into the ultra-violet.

Hence the hotter a star is, the further does its complete or *continuous* spectrum lengthen out towards the ultra-violet, and the less is it absorbed by cooler vapours in its atmosphere.

Now to deal with three of the main groups of stars, we find the following very general result:—

Gaseous stars	Longest spectrum.
Metallic stars	Medium spectrum.
Carbon stars	Shortest spectrum.

We have now associated two different series of phenomena, and we are enabled to make the following statement:—

Gaseous stars	Highest temperature.
Metallic stars	Medium temperature.
Carbon stars	Lowest temperature.

Hence the differences in apparent chemical constitutions are associated with differences of temperature.

Can we associate with the two to which I have already called attention still a third class of facts?

Laboratory work enables us to do this. When I began my inquiries the idea was, one gas or vapour one spectrum. We now know that this is not true; the systems of bright lines given out by radiating substances change with the temperature.

We can get the spectrum of a well-known compound substance—say carbonic oxide; it is one special to the compound; we increase the temperature so as to break up the compound, and we then get the spectra of its constituents, carbon and oxygen.

But the important thing in the present connection is that the spectra of the chemical elements behave exactly in the same way as the spectra of known compounds do when we employ temperatures far higher than those which break up the compounds; and indeed in some cases the changes are more marked. For brevity I will take for purposes of illustration three substances, and deal with one increase of temperature only, a considerable one and obtainable by rendering a substance incandescent, first by a direct current of electricity, as happens in the so-called "arc lamps" employed in electric lighting, and next by the employment of a powerful induction coil and battery of leyden jars. In laboratory parlance we pass thus from the arc to the jar-spark. In the case of magnesium, iron and calcium, the changes observed on passing from the temperature of the arc to that of the spark have been minutely observed. In each, new lines are added or old ones are intensified at the higher temperature. Such lines have been termed *enhanced lines*.

These enhanced lines are not seen alone: outside the region of high temperature in which they are produced, the cooling vapours give us the cool lines. Still we can conceive the enhanced lines to be seen alone at the highest temperature in a space sufficiently shielded from the action of all lower temperatures, but such a shielding is beyond our laboratory expedients.

In watching the appearance of these special enhanced lines in stellar spectra we have a third series of phenomena available, and we find that the results are absolutely in harmony with what has gone before. Thus

Gaseous stars ..	Highest temperature...	Strong helium and faint enhanced lines.
Metallic stars ...	Medium temperature	Feeble helium and strong enhanced lines. No helium and strong arc lines.
Carbon stars ..	Lowest temperature...	Faint arc lines.

It is clear now, not only that the spectral changes in stars are associated with, or produced by, changes of temperature, but that the study of the enhanced spark and the arc lines lands us in the possibility of a rigorous stellar thermometry, such lines being more easy to observe than the relative lengths of spectrum.

Accepting this, we can take a long stride forward and, by carefully studying the chemical revelations of the spectrum, classify the stars along a line of temperature. But which line? Were all the stars, in popular phraseology, created hot? If so, we should simply deal with the running down of temperature, and because all the hottest stars are chemically alike, all cooler stars would be alike. But there are two very distinct groups of coolest stars; and since there are two different kinds of coolest stars, and only one kind of hottest star, it can not be merely a question either of a running up or a running down of temperature.

Many years of very detailed inquiry have convinced me that all stars save the hottest must be sorted out into two series—those getting hotter and those, like our sun, getting cooler, and that the hottest stage in the history of a star is reached near the middle of its life.

The method of inquiry adopted has been to compare large-scale photographs of the spectra of the differ

stars, taken by my assistants at South Kensington; the complete harmony of the results obtained along various lines of other work carries conviction with it.

We find ourselves here in the presence of minute details exhibiting the workings of a chemical law, associated distinctly with temperature; and more than this, we are also in the presence of high temperature furnaces, entirely shielded by their vastness from the presence of those distracting phenomena which we are never free from in the most perfect conditions of experiment we can get here.

What, then, is the chemical law? It is this. In the very hottest stars we deal with the gases hydrogen, helium, and doubtless others still unknown, almost exclusively. At the next lowest temperatures we find these gases being replaced by metals in the state in which they are observed in our laboratories when the most powerful jar-spark is employed. At a lower temperature still the gases almost disappear entirely, and the metals exist in the state produced by the electric arc. Certain typical stars showing these chemical changes may be arranged as follows:

Stars getting hotter.	Hottest stars.	Stars cooling.
	Bellatrix	
ζ Tauri		β Persei
Rigel		γ Lyra
α Cygni		Castor
γ Cygni		Procyon
α Orionis		Arcturus and Sun

This, then, is the result of our first inquiry into the existence of the various chemical elements in the atmospheres of stars generally. We get a great diversity, and we know that this diversity accompanies changes of temperature. We have also found that the sun, which we independently know to be a cooling star, and Arcturus, are identical chemically.

We have now dealt with the presence of the various chemical elements, generally, in the atmospheres of stars. The next point we have to consider is whether the absorption which the spectrum indicates for us takes place from top to bottom of the atmosphere, or only in certain levels.

In many of these stars the atmosphere may be millions of miles high. In each the chemical substances in the hottest and coldest portions *may* be vastly different; the region, therefore, in which this absorption takes place, which spectroscopically enables us to discriminate star from star, must be accurately known before we can obtain the greatest amount of information from our inquiries.

Our next duty then clearly is to study the sun—a star so near us that we can examine the *different parts* of its atmosphere, which we cannot do in the case of the more distant stars. By doing this we may secure facts which will enable us to ascertain in what parts of the atmosphere the absorption takes place which produces the various phenomena on which the chemical classification has been based.

It is obvious that the general spectrum of the sun, like that of stars generally, is built up of all the absorptions *which can make themselves felt* in every layer of its atmosphere from bottom to top, that is from the photosphere to the outermost part of the corona. Let me remind you that this spectrum is *changeless* from year to year.

Now sun-spots are disturbances produced in the photosphere; and the chromosphere, with its disturbances, called prominences, lies directly above it. Here, then, we are dealing with the lowest part of the sun's atmosphere. We find first of all that in opposition to the changeless general spectrum, great changes occur with the sun-spot period, both in the spots and chromosphere.

The spot spectrum is indicated, as was found in 1866, by the widening of certain lines; the chromospheric spectrum, as was found in 1868, by the appearance at the sun's limb of certain bright lines. In both cases the lines affected seen at any one time are relatively few in number.

In the spot spectrum, at a sun-spot minimum, we find iron lines chiefly affected; at a maximum they are chiefly of unknown or unfamiliar origin. At the present moment the affected lines are those recorded in the spectra of vanadium and scandium, with others never seen in a laboratory. That we are here far away from terrestrial chemical conditions is evidenced by the fact that there is not a gramme of scandium available for laboratory use in the world at the present time.

Then we have the spectrum of the prominences and the chromosphere. That spectrum we are enabled to observe every day when the sun shines, as conveniently as we can observe that of sun-spots. The chromosphere is full of marvels. At first, when our knowledge of spectra was very much more restricted than now, almost all the lines observed were unknown. In 1868 I saw a line in the yellow, which I found behaved very much like hydrogen, though I could prove that it was not due to hydrogen; for laboratory use the substance which gave rise to it I called helium. Next year I saw a line in the green at 1474 of Kirchhoff's scale. That was an unknown line, but in some subsequent researches I traced it to iron. From that day to this we have observed a large number of lines. They have gradually been dragged out from the region of the unknown, and many are now recognised as enhanced lines, to which I have already called attention as appearing in the spectra of metals at a very high temperature.

But useful as the method of observing the chromosphere without an eclipse, which enables us

"... to feel from world to world,"

as Tennyson has put it, has proved, we want an eclipse to see it face to face.

A tremendous flood of light has been thrown upon it by the use of large instruments constructed on a plan devised by Respighi and myself in 1871. These give us an image of the chromosphere painted in each one of its radiations, so that the exact locus of each chemical layer is revealed. One of the instruments employed during the Indian eclipse of this year is that used in photographing the spectra of stars, so that it is now easy to place photographs of the spectra of the chromosphere obtained during a total eclipse and of the various stars side by side.

I have already pointed out that the chemical classification indicated that the stars next above the sun in temperature are represented by γ Cygni and Procyon, one on the ascending, the other on the descending branch of the temperature curve.

Studying the spectra photographed during the eclipse of this year we see that practically the lower part of the sun's atmosphere, if present by itself, would give us the lines which specialise the spectra of γ Cygni or Procyon.

I recognise in this result a veritable Rosetta stone which will enable us to read the celestial hieroglyphics presented to us in stellar spectra, and help us to study the spectra and to get at results much more distinctly and certainly than ever before.

One of the most important conclusions we draw from the Indian eclipse is that, *for some reason or other*, the lowest hottest part of the sun's atmosphere does not write its record among the lines which build up the general spectrum so effectively as does a higher one.

There was another point especially important on which we hoped for information, and that was this. Up to the employment of the prismatic camera insufficient attention had been directed to the fact that in observations made by an ordinary spectroscope, no true measure of the height to which the vapours or gases

extended above the sun could be obtained; early observations, in fact, showed the existence of glare between the observer and the dark moon; hence it must exist between us and the sun's surroundings.

The prismatic camera gets rid of the effects of this glare, and its results indicate that the effective absorbing layer—that, namely, which gives rise to the Fraunhofer lines—is much more restricted in thickness than was to be gathered from the early observations.

We are justified in extending these general conclusions to all the stars that shine in the heavens.

So much then, in brief, for solar teachings in relation to the record of the absorption of the lower parts of stellar atmospheres.

Let us next turn to the higher portions of the solar surroundings to see if we can get any effective help from them.

In this matter we are dependent absolutely upon eclipses, and I shall fulfil my task very badly if I do not show you that the phenomena then observable when the so-called corona is visible, full of awe and grandeur to all, are also full of precious teaching to the student of science. This also varies like the spots and prominences with the sun-spot period.

It happened that I was the only person that saw both the eclipse of 1871 at the maximum of the sun-spot period and that of 1878 at minimum; the corona of 1871 was as distinct from the corona of 1878 as anything could be. In 1871 we got nothing but bright lines indicating the presence of gases; namely hydrogen and another, since provisionally called coronium. In 1878 we got no bright lines at all, so I stated that probably the changes in the chemistry and appearance of the corona would be found to be dependent upon the sun-spot period, and recent work has borne out that suggestion.

I have now specially to refer to the corona as observed and photographed this year in India by means of the prismatic camera, remarking that an important point in the use of the prismatic camera is that it enables us to separate the spectrum of the corona from that of the prominences.

One of the chief results obtained is the determination of the position of several lines of probably more than one new gas, which, so far, have not been recognised as existing on the earth.

Like the lowest hottest layer, *for some reason or other*, this upper layer does not write its record among the lines which build up the general spectrum.

General results regarding the locus of absorption in stellar atmospheres.

We learn from the sun, then, that the absorption which defines the spectrum of a star is the absorption of a middle region, one shielded both from the highest temperature of the lowest reaches of the atmosphere where most tremendous changes are continually going on, and the external region where the temperature must be low, and where the metallic vapours must condense.

If this is true for the sun it must be equally true for Arcturus, which exactly resembles it. I go further than this, and say that in the presence of such definite results as those I have brought before you, it is not philosophical to assume that the absorption may take place at the bottom of the atmosphere of one star, or at the top of the atmosphere of another. The *onus probandi* rests upon those who hold such views.

So far I have only dealt in detail with the hotter stars, but I have pointed out that we have two distinct kinds of coolest ones, the evidence of their much lower temperature being the shortness of their spectra. In one of these groups we deal with absorption alone, as in those already considered; we find an important break in the phenomena observed; helium, hydrogen and metals have practically disappeared, and we deal with carbon absorption alone.

But the other group of coolest stars presents us with quite new phenomena. We no longer deal with absorption alone, but accompanying it we have radiation, so that the spectra contain both dark lines and bright ones. Now since such spectra are visible in the case of new stars, the ephemera of the skies, which may be said to exist only for an instant relatively, and when the disturbance which gives rise to their sudden appearance has ceased, we find their places occupied by nebulae, we cannot be dealing here with stars like the sun, which has already taken some millions of years to slowly cool, and requires more millions to complete the process into invisibility.

The bright lines seen in the large number of permanent stars which resemble these fleeting ones—*new stars*, as they are called—are those discerned in the once mysterious nebulae which, so far from being stars, were supposed not many years ago to represent a special order of created things.

Now the nebulae differ from stars generally in the fact that in their spectra we have practically to deal with radiation alone, we study them by their bright lines, the conditions which produce the absorption by which we study the chemistry of the hottest stars are absent.

A new view of stars.

Here then we are driven to the perfectly new idea that some of the cooler bodies in the heavens the temperature of which is increasing and which appear to us as stars, are really disturbed nebulae.

What then is the chemistry of the nebulae? It is mainly gaseous; the lines of helium and hydrogen and the flutings of carbon, already studied by their absorption in the groups of stars to which I have already referred, are present as bright ones.

The presence of the lines of the metals iron, calcium, and probably magnesium, shows us that we are not dealing with gases merely.

Of the enhanced metallic lines there are none, only the low temperature lines are present, so far as we yet know. The temperature then is low, and lowest of all in those nebulae where carbon flutings are seen almost alone.

A new view of nebulae.

Passing over the old views, among them one that the nebulae were holes in something dark which enabled us to see something bright beyond, and another that they were composed of a fiery fluid, I may say that not long ago they were supposed to be masses of gases only, existing at a very high temperature.

Now, since gases may glow at a low temperature as well as at a high one, the temperature evidence must depend upon the presence of cool metallic lines and the absence of the enhanced ones.

The nebulae, then, are relatively cool collections of some of the permanent gases and of some cool metallic vapours, and both gases and metals are precisely those I have referred to as writing their records most visibly in stellar atmospheres.

Now can we get more information concerning this association of certain gases and metals? In laboratory work it is abundantly recognised that all meteorites (and many minerals) when slightly heated give out permanent gases, and under certain conditions the spectrum of the nebulae may in this way be closely approximated to. I have not time to labour this point, but I may say that a discussion of all the available observations to my mind

demonstrates the truth of the suggestion, made many years ago by Prof. Tait before any spectroscopic facts were available, that the nebulae are masses of meteorites rendered hot by collisions.

Surely human knowledge is all the richer for this indication of the connection between the nebulae, hitherto the most mysterious bodies in the skies, and the "stones that fall from heaven."

Celestial evolution.

But this is, after all, only a stepping-stone, important though it be. It leads us to a vast generalisation. If the nebulae are thus composed, they are bound to condense to centres however vast their initial proportions, however irregular the first distribution of the cosmic clouds which compose them; each pair of meteorites in collision puts us in mental possession of what the final stage must be. We begin with a feeble absorption of metallic vapours round each meteorite in collision; the space between the meteorites is filled with the permanent gases driven out further afield and having no power to condense. Hence dark metallic and bright gas lines. As time goes on, the former must predominate, for the whole swarm of meteorites will then form a gaseous sphere with a strongly heated centre, the light of which will be absorbed by the exterior vapour.

The temperature-order of the group of stars with bright lines as well as dark ones in their spectra, has been traced, and typical stars indicating the chemical changes have been as carefully studied as those in which absorption phenomena are visible alone, so that now there are no breaks in the line connecting the nebulae with the stars on the verge of extinction.

Here we are brought to another tremendous outcome, that of the evolution of all cosmical bodies from meteorites, the various stages recorded by the spectra being brought about by the various conditions which follow from the conditions.

These are shortly that at first collisions produce luminosity among the colliding particles of the swarm, and the permanent gases are given off and fill the interspaces. As condensation goes on, the temperature at the centre of condensation always increasing, all the meteorites in time are driven into a state of gas. The meteoritic bombardment practically now ceases for lack of material, and the future history of the mass of gas is that of a cooling body, the violent motions in the atmosphere while condensation was going on now being replaced by a relative calm.

The absorption phenomena in stellar spectra are not identical at the same mean temperature on the ascending and descending sides of the curve, on account of the tremendous difference in the physical conditions.

In a condensing swarm, the centre of which is undergoing meteoritic bombardment from all sides, there cannot be the equivalent of the solar chromosphere; the whole mass is made up of heterogeneous vapour at different temperatures, and moving with different velocities in different regions.

In a condensed swarm, of which we can take the sun as a type, all action produced from without has practically ceased; we get relatively a quiet atmosphere and an orderly assortment of the vapours from top to bottom, disturbed only by the fall of condensed metallic vapours. But still, on the view that the differences in the spectra of the heavenly bodies chiefly represent differences in degree of condensation and temperature, there can be, *au fond*, no great chemical difference between bodies of increasing and bodies of decreasing temperature. Hence, we find at equal mean temperatures on opposite sides of the temperature curve, this chemical similarity of the absorbing vapours proved by many points of resemblance in the spectra, especially the identical behaviour of the enhanced metallic and cleveite lines.

Celestial dissociation.

The time you were good enough to put at my disposal is now exhausted, but I cannot conclude without stating that I have not yet exhausted all the conceptions of a high order to which Fraunhofer's apparently useless observation has led us.

The work which to my mind has demonstrated the evolution of the cosmos as we know it from swarms of meteorites, has also suggested a chemical evolution equally majestic in its simplicity.

A quarter of a century ago I pointed out that all the facts then available suggested the hypothesis that in the atmospheres of the sun and stars various degrees of "celestial dissociation" were at work, a "dissociation" which prevented the coming together of the finest particles of matter which at the temperature of the earth and at all artificial temperatures yet attained here compose the metals, the metalloids and compounds.

On this hypothesis the so-called atoms of the chemist represent not the origins of things, but only early stages of the evolutionary process.

At the present time we have tens of thousands of facts which were not available twenty-five years ago. All these go to the support of the hypothesis, and among them I must indicate the results obtained at the last eclipse, dealing with the atmosphere of the sun in relation to that of the various stars of higher temperature to which I called your attention. In this way we can easily explain the enhanced lines of iron existing practically alone in Alpha Cygni. I have yet to learn any other explanation.

I have nothing to take back either from what I then said or what I have said since on this subject, and although the view is not yet accepted, I am glad to know that many other lines of work which are now being prosecuted tend to favour it.

I have no hesitation in expressing my conviction that in a not distant future the inorganic evolution to which we have been finally led by following up Fraunhofer's useless experiment, will take its natural place side by side with that organic evolution the demonstration of which has been one of the glories of the nineteenth century.

And finally now comes the moral of my address. If I have helped to show that observations having no immediate practical bearing may yet help on the thought of mankind, and that this is a thing worth the doing, let me express a hope that such work shall find no small place in the future University of Birmingham.

DIFFUSION IN RELATION TO WORK.

IN this month's *Philosophical Magazine* Mr. A. Griffiths has an interesting paper on diffusion convection, in which he suggests an indirect method of measuring rates of diffusion of liquids, and concludes with the following deduction from the fact that diffusion sometimes produces convection currents and sometimes does not:—"Does not this indicate that the heat produced on mixing a solution with water depends on how the mixing takes place? Is the matter connected with a sort of surface-tension existing in the spaces between a strong and a weak solution?"

Mr. Griffiths does not seem to have observed that his investigation applies quite well to gases as to liquids, and that his indirect method of measuring rates of diffusion is applicable to gases. In the case of gases there can be sensible surface-tension, and, as the theory of diffusion in gases is quite simple, there is no serious difficulty in seeing how there is a difference between different ways of mixing them.

It is generally known that two different gases may be mixed by irreversible, or by, at least, partially reversible,

processes. They may be allowed to diffuse freely into one another, or may be separated by a porous partition. In the latter case a considerable difference of pressure may be produced between different parts of the space containing them, and this difference of pressure can be used to do work. The final condition in this case is, of course, cooler than if the gases did no external work. In the same way a solution diffusing into water may do so without doing external work, or it may do so by a reversible process, through a semi-permeable diaphragm, producing considerable differences of pressure, which may be used to do work. The final condition in this latter case would, of course, be cooler than in the former case of inter-diffusion without doing external work. Now whenever convection currents are produced, these are to some extent reversible. We might put vanes into the liquid to be moved by the currents and to do work outside the liquid, and by reversing this we would reverse the convection currents. Hence any method of mixing in which convection currents are produced, which do work or produce heat outside the liquid, will necessarily produce less heat in the liquid than a method of mixing in which there are either no convection currents, or these produce heat by viscous flow inside the liquid.

That we can, at pleasure, either use the diffusion of two gases into one another to do external work or not, is really not different from the case of a single gas expanding into a larger volume. We may do work by this expansion and cool the gas, or we may allow the gas, as in Joule's experiments, to expand into a larger volume without doing external work, and in this case there is only a very small change of temperature.

In these cases it is a question of change of entropy in the system, which can either be effected by an irreversible process in which no work is done, or by a variety of other processes, more or less reversible, in which the more reversible they are the more work can be done. In the case of producing convection currents, or, in general, of diffusion of a heavy fluid upwards into a lighter one, the amount of heat produced would not be exactly the same as if gravity were not acting: the centre of gravity of the system is raised by diffusion. Now in Mr. Griffiths's case, and in the case of diffusion currents generally, this raising of the centre of gravity takes place throughout part of the space considered by diffusion, and the centre of gravity is continually falling down again in the convection currents. Hence the work that can be done by the convection currents is part of the work that was done by diffusion against gravity. In the case of diffusion without convection currents, we might use the whole of this work done against gravity, by which the centre of gravity of the system has been raised, to do external work. If, for example, the containing vessel were supported at its centre of gravity, in the unmixed condition, the centre of gravity would, after diffusion, be above the point of support, and the vessel and its contents might be arranged to turn round the support doing work during the fall of the centre of gravity to its original level. Another way of utilising the rise is to allow the fluid to flow into another broader vessel until its centre of gravity has returned to the original level. The thing to be specially observed is, that the amount by which the centre of gravity is raised depends entirely upon the shape of the vessel. If it be tall, the centre of gravity will be raised a great deal; while if it be low, the centre of gravity will be only slightly raised. By causing diffusion to take place in a tall thin vessel, the final temperature will be lower than in a broad low one, not on account of any superficial tensions, but on account of the work done against gravity. In Mr. Griffiths's methods diffusion is continually taking place along tall thin vessels, and convection currents lowering the centre of gravity again by flow into broad ones. Geo. Fras. FitzGerald.

THE EXPECTED METEORIC SHOWER.

The imminent return of the Leonids once more attracts us to prepare for their observation and discuss their phenomena. The circumstances this year will be much more favourable, all round, than they were in 1897, but our prospects of witnessing a really brilliant return appear to be somewhat slender. No doubt, on the morning of November 15, meteors will appear in sufficient abundance to gratify moderate expectation, but the conditions scarcely warrant the influence that we are to have a grand display. We must wait until 1899 or 1900 to see the shower at its best. In 1832 it is true Dawes saw many astonishingly fine meteors; and well he might, for the parent comet of the Leonids was very near that section of the orbit which the earth intersected in the year named. In 1865 we passed through a region of the stream some way in advance of the comet, for the latter arrived at its descending node about two months after the earth had crossed the point. There was nothing deserving the title of a great meteoric shower on that occasion. But there was certainly an unusual number of fine shooting-stars, the majority of the objects observed being as bright as, or brighter than, stars of the first magnitude. At Greenwich it was estimated that more than 1000 meteors must have been visible on the morning of November 13. Mr. Knott, observing at Cuckfield in Sussex, estimated the number as more than one per minute for two observers. According to some other accounts the richness of the display far exceeded this, for a captain of a British ship, near the West Indies, wrote to say that the heavens were in a blaze with shooting-stars from 8 p.m. on November 12 to 5 next morning. But accounts of the latter description are often exaggerated, and it is always unsafe to draw any definite conclusions from them.

At the approaching return the earth crosses the meteoric orbit still further in front of the comet than it did in 1865. In fact the comet will have five or six months' journey to run at its highest rate of speed before it reaches its descending node. This is not allowing for any perturbations which the comet has experienced since 1866, and there is no doubt that some serious disturbances have been introduced, particularly, by Saturn and Jupiter.

It seems that in July 1895, the comet approached to within 45 millions of miles of Saturn, and though the former has not passed so near as this to Jupiter, both planets have exercised a very appreciable influence both on the comet and its associated meteoric stream. Dr. Berberich gives these conclusions in an important paper published in *Ast. Nach.*, 3526, and states as a result of his investigation that the meteor shower will appear 21 hours late in 1898 and 26 hours behind time in 1899. The comet of Tempel (1866 I.) is not, according to Dr. Berberich, likely to be observed at the ensuing return to perihelion, as it will present itself under unfavourable conditions. Dr. Berberich's results are interesting as showing the necessity for expecting the meteors on the mornings of the 15th and 16th, rather than on earlier dates. His conclusions seem strengthened by the fact that last year a pretty strong shower of Leonids was witnessed just before sunrise on the morning of the 15th, whereas very few were seen on the previous morning.

Under all the circumstances a very rich shower can hardly be expected. Our historical records do not warrant the assumption that the section of the orbit in the van of the comet is thickly strewn with meteoric particles. In the comet's wake, for an enormous distance, the material appears to be densely distributed. This was sufficiently attested by the succession of three brilliant displays of 1866, 1867 and 1868.

Meteoric and cometary phenomena are, however, somewhat unstable in character, and certainly variable

in their manifestations. They are quite capable of giving surprises. More meteors may now precede the cometary nucleus than the number there a generation ago, though the period is a comparatively short one, and comprises only one revolution of the swarm. There is one highly favouring circumstance this year, and that is the absence of moonlight. If the atmosphere is also free from cloud, the nights following the 14th and 15th will afford a splendid opportunity both for the visual observer and the photographic manipulator. I believe the night of the 14th will turn out the most productive, and especially the latter part of it forming the few hours before sunrise on the 15th.

Ordinary observers, while watching the meteors, will be usefully employed in determining, as accurately as possible, the time when the maximum in point of numbers is reached. The meteors should be counted at short intervals, and the horary rates of apparition during the night ascertained. The position of the radiant point is already well known; a mean of seventy values places it at R.A. 149° 28′, Dec. 22° 52′+, so that it is centrally within the curve of the "Sickle" of Leo, and close to the star *x* Leonis (Mag. 5·7) of Bode or Piazzi IX. 230.

It is especially to be hoped that attempts to obtain determinations of the radiant point by photography will be successful. The want of success in previous efforts has been very disappointing. Thus Mr. W. H. Pickering writes in *Popular Astronomy*, that on November 13, 1897, though he exposed eighty-one plates, only two meteor trails were secured. No doubt there are difficulties to be overcome; but as soon as the photographic method can be successfully utilised on a great meteoric shower, and a sufficient number of trails obtained to indicate a really good radiant, the visual method will have to be abandoned in its favour. It will be a long time hence, if ever, that the photographic plate will supersede the eye in ordinary meteoric observation; but in the case of a display such as the Leonids can furnish, the new method seems to promise well as regards the great accuracy of its records, though hitherto the latter have been exceedingly meagre.

W. F. DENNING.

MR. LATIMER CLARK, F.R.S.

ON Sunday, October 30, Mr. Latimer Clark, F.R.S., died very suddenly at his residence at Kensington, in his seventy-sixth year. His loss will be keenly felt by the various learned societies of which he was a member; especially by the Institution of Electrical Engineers, who claimed him as a founder and past-president. The name of Latimer Clark is familiar to all who during the past half-century have watched the various phases of progress in the science and practice of electrical engineering. Submarine cable engineers associate it with inventions that relate to every branch of their profession, from the process of sheathing the "core," to the last refinements of testing; and the constructors of land-lines still recognise the "Latimer Clark" double-bell insulator as a type universally accepted His book, written in conjunction with the late Robert Sabine, on "Electrical Tables and Formulae," is to be found in every electrician's library, and in every cable-factory and telegraph testing-station in the world; his "approximate method" of fault-testing on submarine cables, by applying two successive potential differences, was an important step in the development of the modern empirical but nevertheless remarkably exact system of testing by two applications of different battery power; and his test of the electrical condition of "joints" in cable core is, under the name of "the accumulation method," still in daily use at cable works and on board ship. Another of his valuable contributions to telegraph progress is his study of the errors due to the inductive action of a galvanometer-needle upon its own coil when using shunts of different values, in a series of comparative "discharges." To this must be added his important modification of Poggendorff's method of comparing electro-motive forces, and the introduction, with this test, of the well-known potentiometer that bears his name. This instrument is perhaps associated in our minds rather with the laboratory than with the cable-testing room; and, moreover, it is here in the physical laboratory that we discover what is undoubtedly the best-known of Mr. Latimer Clark's inventions: the zinc-mercury standard cell. The vast amount of work that has been done, the modifications suggested, and the pages written in regard to this small apparatus, might well lead the uninitiated to suppose that it contains some potent *talia azman* to which electricians are for ever looking for revelation and mysteries. It happens to be merely the electricians' practical standard of potential-difference; but to those who care to study such things, it is still full of the mystery of the origin and meaning of contact electro-motive force.

The written and legendary history of the early days of electric telegraphs, over land and under sea, shows how closely Mr. Latimer Clark was associated with this work, both at home and abroad. Success did not always reward the efforts of the telegraph engineer, even in those times; for although commercial competition did not then exist to its present extent, there were all the difficulties of inexperience to be fought against. Success as regards the technical details of construction and working, came sooner than financial success. Estimating the cost of land-lines was beset with the almost insurmountable difficulties of transport and commissariat in countries savage and unexplored. Mr. Latimer Clark, in those pioneer days, was one upon whom the brunt of these reverses at first fell somewhat heavily. All honour to him and to his comrades; they fought for the greatest achievement in the world's history. R. A.

THE TREASURERSHIP OF THE ROYAL SOCIETY.

IN the list of the proposed Council of the Royal Society for the ensuing year will be noticed a change in the Treasurership. Sir John Evans, K.C.B., retires, and the Council proposes to replace him by Mr. Kempe. Concerning this proposal the following letter has appeared in the *Times*:—

Sir,—The list of officers of the Royal Society proposed for election at the general meeting at the end of this month, published in the *Times* of Friday last, will not surprise any Fellow who is acquainted with the inner history of the society during the past few years, but in the change of *personnel* of the treasurership suggested it will astonish the great body of Fellows and may well arouse misgiving, if not anxiety, in the mind of the public—misgiving not to be lessened by the veiled *communiqué*, intended, apparently, to allay apprehension, which appeared in a certain section of the London press on Saturday.

The treasurer of the society is, like the two secretaries, a permanent officer, and these three officers have, therefore, a dominant influence in the affairs of the society, the treasurer having place by custom, at any rate next to the president.

Outside the society, too, in those responsible relationships with the public which the position of the society, as representative of science, engenders these permanent officials have a voice, consultative or executive, for the society. The choice, then, of treasurer is a matter of immediate moment to a wider circle than the Fellows of the society, and the nomination to the office by the present officers and council may therefore be fairly submitted for criticism in the *Times*. It is an open secret that an influential protest failed to arrest it.

Assuredly the roll of the society furnishes in abundance names of Fellows well tried in its work and veterans in the cause of science from which, as heretofore, a selection of treasurer could be made which would not only safeguard the interests of the society but also be a guarantee to the public that the best blood of the society was being devoted to the

services it justly claims. Why, then, should choice fall, as it has fallen, upon a comparatively junior Fellow who, whatever his scientific merit, is unknown as a leader in science? Is there no room at present for another planet in the official firmament? Whatever be the cause, a large number of Fellows view with dismay this departure from the wise tradition which required pre-eminence amongst the eminent in science as the passport to the position of officer in the Royal Society, and to many the nomination, if it be confirmed, will appear a damaging blow to the society's prestige.

It may be that notwithstanding the protest referred to those responsible for the nomination do not realise its full significance and the feeling it has stirred. If this be as strong as it appears there is provided by the constitution of the society at the general meeting on the 30th an opportunity for its expression.

I am, &c., F.R.S.

It may be remarked that on looking back into the history of the Society, we find the last four Treasurers to have been—

General Sabine	1850
Prof. W. A. Miller	1861
Dr. Spottiswoode	1870
Sir John Evans	1878

NOTES.

THE Royal Society's medals have this year been adjudicated as follows:—Copley Medal, Sir William Huggins, F.R.S.; Royal Medals, Rev. John Kerr, F.R.S., Mr. Walter Gardiner, F.R.S.; Rumford Medal, Prof. Oliver Lodge, F.R.S.; Davy Medal, Prof. Johannes Wislicenus, For. Mem. R.S.; Darwin Medal, Prof. Karl Pearson, F.R.S.

AT the anniversary meeting of the Royal Society on November 30, the following names will be recommended for election into the Council of the Society for the year 1899:—President: Lord Lister. Treasurer: Alfred Bray Kempe. Secretaries: Prof. Michael Foster, Prof. Arthur William Rücker. Foreign Secretary: Sir Edward Frankland, K.C.B. Other members of the Council: Prof. Thomas George Bonney, Captain Ettrick William Creak, R.N., Prof. Daniel John Cunningham, Prof. James Dewar, Prof. William Dobinson Halliburton, Prof. William Abbott Herdman, Victor A. H. Horsley, Joseph Larmor, Prof. Nevil Story Maskelyne, Sir Andrew Noble, K.C.B., Prof. Edward Bagnall Poulton, Dr. William James Russell, Prof. Arthur Schuster, Dr. Dukinfield Henry Scott, Dr. George Johnstone Stoney, Prof. Joseph John Thomson.

PROF. OSTWALD will give an address at University College, Gower Street, on Monday next, November 14, at 5 p.m., in the Chemical Theatre. Visitors are invited.

THE appointment of a Commission, consisting mainly of scientific experts, to report upon the plague in India, has already been referred to in these columns (vol. lviii. p. 626). We now learn that Dr. Thomas R. Fraser, F.R.S., Professor of Materia Medica and Clinical Medicine at Edinburgh University, has accepted the duty of president, and with him will be associated two other scientific experts, Dr. Wright, Professor of Pathology at the Army Medical School, Netley, and Dr. Rüffer, who has been for some time head of the Egyptian Sanitary Department at Cairo. Two officers of the Indian Civil Service, Mr. J. P. Hewett, and Mr. A. Cumine, both of whom have had much to do with recent plague affairs in India, have also been appointed to the Commission by the Government of India. The scope of the Commissioners' inquiries will include (1) the origin of the different outbreaks of plague; (2) the manner in which the disease is communicated; (3) the effects of certain prophylactic and curvative serums that have been tried or recommended for the disease. The members of the Commission will reach Bombay towards the end of the present month.

MR. CECIL B. CRAMPTON, of the University of Edinburgh, has been appointed to the position of assistant-keeper in the geological department of the Manchester Museum, Owens College, in succession to Mr. Herbert Bolton.

AT the anniversary meeting of the Mineralogical Society, to be held on Tuesday next, November 15, the election of officers and Council will take place. Prof. A. H. Church, F.R.S., has been nominated president, and Prof. G. D. Liveing, F.R.S., and Dr. Hugo Müller, F.R.S., vice-presidents.

WITH reference to Dr. Calmette's gift of 10,000*l.* to the Pasteur Institute at Lille, mentioned last week, the *British Medical Journal* states that, according to the terms of the deed of gift, the money is to be applied provisionally to the defraying of building expenses till the Municipal Council is in a position to vote the sums required for that purpose. The money is then to be employed in the purchase of material for new researches, or for the maintenance of young men of science who wish to make original researches in the laboratory. Dr. Calmette states that the money which he has thus generously bestowed, represents the profits accruing to him from the application of one of his discoveries in a large distillery at Seclin.

THE new session of the Royal Geographical Society will commence on Monday next, November 14, when addresses upon the subject of a British Antarctic expedition will be given by the President and others. At a meeting on November 28, Mr. C. W. Andrews will give an account of a year's work on Christmas Island. Other papers which are announced are the following:—"Exploration in the Caroline Islands," by F. W. Christian; "Lake Rukwa and Central Africa," by L. A. Wallace; "In Search of Mount Hooker and Mount Brown in the Canadian Rockies," by Dr. Norman Collie, F.R.S.; "Oceans and Continents," by Dr. J. W. Gregory; "Atlantic Highlands of the United States," by Prof. W. M. Davis; "Exploration in Sokotra," by Dr. H. O. Forbes.

DR. H. C. SORBY, F.R.S., who last year completed fifty years' connection with the Sheffield Literary and Philosophical Society, during which period he on several occasions filled the presidential chair, has just received a gratifying testimony of the esteem in which he is held locally as well as in the broad world of science. His admirers have had his portrait painted, and presented it to him with an illuminated address on Tuesday in last week. The portrait represents Dr. Sorby seated, and in his scarlet academic gown. The inscription at the foot of the frame is as follows:—"H. Clifton Sorby, LL.D., F.R.S. (1847–1897). This portrait was painted to celebrate Dr. Sorby's fifty years' connection with the Sheffield Literary and Philosophical Society, and to commemorate his world-wide scientific reputation. Funds for the purpose were provided by subscription amongst the proprietors and members of the Society. The artist was Mrs. M. L. Waller, and the presentation was made on behalf of the subscribers by the Lord Mayor of Sheffield on November 1, 1898."

THE first meeting of the new session of the Society of Arts will be held on Wednesday next, November 16, when an address will be delivered by Sir John Wolfe Barry, K.C.B., F.R.S., Chairman of the Council. Among the subjects of papers to be read before Christmas are: "Long Distance Transmission of Electric Power," by Prof. George Forbes, F.R.S.; "Photographic Developers and Development," by Mr. C. H. Bothamley. The papers for meetings after Christmas include: "Tuberculosis in Animals," by Mr. W. Hunting; "Canals and Inland Navigation in the United Kingdom," by Mr. L. F. Vernon-Harcourt; "Preservation of Timber," by Mr. S. B. Boulton; "Electric Traction and its Application to

Railway Work," by Mr. Philip Dawson; "Coal Supplies," by Mr. T. Forster Brown; "Wireless Telegraphy," by Mr. W. H. Preece, C.B., F.R.S.; "Leadless Glazes," by Mr. Wilton P. Rix. The following courses of Cantor lectures will be delivered: "Acetylene," by Prof. Vivian B. Lewes; "Bacterial Purification of Sewage," by Dr. Samuel Rideal; "Cycle Construction and Design," by Mr. Archibald Sharp; "Leather Manufacture," by Prof. Henry R. Procter.

Writing in the *Chemical News* "On the supposed new gas, Etherion," described by Mr. Charles F. Brush at the recent Boston meeting of the American Association, Sir William Crookes concludes as follows:—"On the evidence at present available, I consider it more probable that etherion is water vapour than that it is a new elementary gas, and this is corroborated by the observations made by Mr. Brush, that etherion is absorbed by phosphoric acid and soda-lime, as well as by the powdered glass from which it has previously been driven off by heat."

Mr. John S. Budgett, who accompanied Mr. Graham Kerr in his recent successful expedition to Paraguay, has left England, under instructions of the Zoological Society, for a winter visit to the Gambia, in order to obtain information concerning the Antelopes and other larger mammals of that Colony. Mr. Budgett will also make a collection of the fishes of the River Gambia, concerning which little is at present known, and of the other zoological products of the district.

The expedition of Mr. Harrington and Dr. Hunt, of Columbia University, New York, to Egypt, referred to last week, resulted in bringing back an admirable collection of Nile fishes, and other zoological materials, but was not successful in its chief object, which was to obtain a set of the embryonic stages of *Polypterus*. Although these naturalists remained in the Delta until August 30, and adult specimens of this fish were obtained as late as that date, the eggs were still immature; so that the important question of the nature of development of *Polypterus* still awaits investigation.

Mr. Stanley S. Flower, lately curator of the Royal Museum, Bangkok, has been appointed director of the Zoological Gardens at Gizeh, Cairo, and has arrived there from Siam to take up his appointment. Mr. Flower, on his voyage westward, brought with him, as a present to the Zoological Society of London, a young Siamang (*Hylobates syndactylus*), which is believed to be the first specimen of this rare ape that has ever reached Europe alive. In 1830 the late Dr. George Bennett started from Singapore, with a living Siamang, which he intended to bring to the Society, but it unfortunately died on its way home.

A new Natural History Museum was opened at King Williams Town, Cape Colony, on October 5. At the conversazione, subsequently held, an address was given by Mr. W. L. Sclater, director of the South African Museum, Capetown. Mr. Sclater, after speaking of museums in general and their origin, gave an account of their introduction into South Africa in 1856 by the foundation, under the governorship of the late Sir George Grey, of the South African Museum at Capetown. Not long afterwards the Albany Museum at Grahamstown was instituted with the object of illustrating the natural products of the eastern provinces of the Colony. There are also museums in South Africa at Port Elizabeth, Bloemfontein, Pretoria, Maritzburg and Durban.

Many students of science will regret to see the announcement that *Science Progress* comes to an end with the number just published. The valuable character of the contributions which have appeared in that magazine since the first number was published in March 1894, are well known in the scientific world; and it is a little disappointing to the publishers to have to confess that there is not sufficient demand for such literature to justify them in continuing to issue it. It is to be regretted that a periodical of this kind, containing articles which assist the advance of scientific knowledge, should have to cease for want of financial support.

Captain J. W. Maxwell Carroll has sent to the *Geographical Journal* (November) a few interesting particulars with reference to ancient stone circles discovered by him in the neighbourhood of Lamin Koto, on the right bank of the Upper Gambia. The stones are in very good preservation, and are regarded with respect by the natives. Prayers are offered in their vicinity on feast days during Ramadan by the Almame, or high priest. The diameter of the circle of stones is eighteen feet, and the stone at which the priest stands is a few feet to the east of the circle. Stone circles were also found by Captain Carroll at Chamen and Palellan. At the latter place a large rectangular stone, twelve feet by four, was discovered. Its height was six feet at one end and four at the other, and its shape suggested that it had been used as a sacrificial altar.

In the *Zeitschrift der Gesellschaft für Erdkunde* we notice, besides minor articles, an account by Dr. C. Lauterbach of the geographical results of the expedition to Kaiser Wilhelm's Land, and a paper, by Dr. Meinardus, on the relation between the winter climates of central and north-western Europe and the waters of the North Atlantic. The latter is an extension of the author's recent paper in the *Meteorologische Zeitschrift*, discussing the observations of Pettersson and Dickson as a possible basis for long-period weather forecasting.

In our issue of September 29 last, we very briefly referred to Dr. Köppen's chart of yearly isotherms and isabnormals of the sea surface. This chart, together with a discussion of its chief features, is reproduced in *Globus* of the 15th ult. The chart shows, in addition to the isotherms, those districts where a temperature anomaly of more than 2° C. exists: the areas where the water is too cold are shaded blue, and those which are too warm are shaded red, while the districts which are thermically neutral are left unshaded. It is seen that between latitude 0° and 40° S., cold currents extend like long tongues from the west coast of South Africa and South America towards the west, while to the north of the equator analogous currents are developed to a much less extent; on the coast of the Sahara the sea-temperature is only slightly below the normal value of the latitude. On the western sides of the oceans, in similar latitudes, there exist warm currents trending northwards. In the South Atlantic the warm and cold currents are nearly equalised. In the South Pacific, the cold current, and in the South Indian Ocean, the warm current, preponderates. This latter feature especially occurs in the northern hemisphere, and more particularly so in the North Atlantic. It is also seen that an area of cold water occurs on the western edge of the warm currents, and between them and the continents, where the latter stretch northwards as far as the zone of westerly winds, viz. on the east coasts of Asia, North and South America. There are many other points of interest, to which we are unable to allude at present.

The Deutsche Seewarte has recently published its twentieth annual report, for the year 1897. The death of Captain Seemann, on September 24 of that year, has been a great loss to the department, as he had for a long time devoted himself to the study and practice of weather telegraphy. A conference of the heads of German meteorological institutions was held at the Seewarte in October 1897, at which special attention was given to the organisation of the meteorological service; a report of

the proceedings has been published. During the year, 283 merchant ships were supplied with registers, and 794 logs were received; the majority of the observations were made in the North Atlantic, but the other oceans are also fairly represented. The observations for the North Atlantic are chiefly utilised in the preparation and publication of results for one-degree squares and of daily synoptic weather charts, both of which works we have already noticed. The Seewarte undertakes the verification of a large number of instruments; it also publishes the results of scientific investigations in the work entitled *Aus dem Archiv der Deutschen Seewarte*. This valuable publication has also already been referred to in our columns. The collection of observations from distant stations is a useful addition to the various other labours of the institution, but the publication of the results has been temporarily retarded by pressure of other work.

PROBLEMS on the deformation of an elastic ellipsoid are known to require for their complete solution functions in working with which a fairly good mathematician may easily go out of his depth. MM. Eugène and François Cosserat, however, send us a note, reprinted from the *Comptes rendus*, in which they show that the particular solutions corresponding to harmonics of the second and third orders, assume comparatively simple forms.

A HIGHLY interesting note by Prof. B. Grassi, on the connection between mosquitoes and malaria, appears in the *Atti dei Lincei*, vii. 7. The theory that these insects disseminate the germs of malaria by their punctures, seems to have been first brought into notice by Laveran; but Dr. Grassi for a long time had doubts on the subject, owing to the absence of malaria from certain districts where mosquitoes abound; Schwetzingen, in Germany, being a notable instance. A careful classification of the various species of gnat found in different districts has now led him to the conclusion that, while certain kinds are not confined to malarious regions, the distribution of others coincides very closely with the distribution of the disease. The common *Culex pipiens* is to be regarded as perfectly innocuous; being most abundant in places from which malaria is absent. On the other hand, a large species (*Anopheles claviger*, Fabr.), known in Italy as "zanzarone," or "moschino," is constantly found associated with malaria, and is most abundant where the disease is most prevalent. In illustration of this fact Dr. Grassi enumerates a number of striking coincidences in which both gnats and the disease are confined to the same limited and well-defined regions. Another disseminator of malaria is *Culex penicillaris*, and the author gives authentic instances in which recorded punctures of this gnat have been followed by febrile symptoms. Certain other species of *Anopheles* are confined to the marshy regions where malaria rages, and two or three additional species of *Culex* are suspected, but on less conclusive evidence. The fact is mentioned that *Anopheles claviger* confines its attacks chiefly to the evening after sunset, and in this circumstance the old superstition that it is dangerous to fall asleep in malarious regions just after sunset, finds a ready explanation. These facts open up new hopes that it may be possible to stamp out malaria by taking proper steps for the destruction of mosquito larvae in districts where dangerous species abound.

THE annual report for 1896-97 on British New Guinea (-9046-5) contains only a few notes of interest to science. The reports of visits of inspection are not so full as in previous years, and there are the ominous footnotes "not printed" relating to several documents of interest. The natives of the lower villages of the Mambare River are very untrustworthy. It was during the visit to this district that the inspectors "for the first time learned how the natives make the hole for the reception of the wooden handle in stone clubs. It is chipped out by means of a small stone about the size and nearly of the shape of a rifle bullet." On the crossing of the Chirima they were visited by about one hundred natives from the village of Neneba. They are the only tribe that actually live on a spur of Mount Scratchley. They are somewhat darker in tint than the coast people, but distinctly lighter than the average Fly River man. They are of fair size and wiry in build. No wavy-haired native was seen in that part of the country, and young men wear the eyebrows, while the elders have whiskers. The features are good and not irregular. The men wear the T-bandage, and the women, in addition to this, wear a petticoat and a mantle. The chief ornaments are earrings made of lizards' tails, and cigarette-holders carried in the lobe of the ear. They had the bow and arrow, and stone clubs, but, like many other bow and arrow tribes, they have no pottery. The floors of their houses are six or eight feet above the ground. At the village of Gosisi, on the Vanapa, the natives did not appear to know of any place or people on the other side of the Owen Stanley range. The men of these tribes have remarkable physical proportions and strength.

AN interesting pamphlet upon the temperance question, from the pen of Dr. Archdall Reid, has just reached us. It is entitled "The Temperance Question from a Biological Standpoint." The author bases his theories and conclusions upon Weissmanism, viz. upon the assumption that inborn or congenital characters alone are transmitted to the offspring, acquired characters not being transmitted. Man is still undergoing evolution at the present day, and this, according to the author, mostly consists in the acquisition by him of immunity against disease or the effect of powerful drugs, including harmful narcotics. Alcohol is a harmful narcotic; from this it follows that one of the directions which the evolution of man is taking at the present day is the acquisition of immunity against alcohol, and this takes the special form of a diminution of the "normal" craving for alcohol. According to Dr. Reid the longer a race has had alcohol, and the easier and more abundant its supply, the more sober it is. For instance, the grape-growing southern Europeans are at the present time more sober than the races of northern Europe, where alcohol is more difficult to obtain, although formerly they were quite as drunken. They have become now immune to alcohol. The method by which this immunity has come about is naturally, from the point of view of the temperance reformer, of the utmost importance. Since, if it could only be imitated successfully, the temperance question would be solved. According to Dr. Reid this diminution of the craving for alcohol has been produced by the action of natural selection working in the presence of an abundant supply of the harmful substance in question. Any cause which reduces the supply of alcohol, or in any way increases the difficulty of obtaining it, in that it hampers the action of natural selection, tends to perpetuate drunkenness rather than to produce temperance. This truly dreadful picture of the world, or rather all races not yet immune, becoming "thoroughly drunken before they can hope to become thoroughly sober," can, to some extent, be mitigated by artificial selection. The innate drunkard, when found out by letting everybody have free access to alcohol, must be treated as a lunatic, and above all not be allowed to procreate. By this means the alcohol tainted "germ plasm" will finally be eliminated, and the race will become immune to alcohol.

THE older entomologists used to complain that the *Lepidoptera* were a peculiarly difficult order to classify, owing to the want of any salient characters; but now that the details of their structure are more minutely studied, the difficulty is rather to decide on the importance to be attached to the structure of particular organs. Even the eggs are now taken into account in classification, and also the larvae in their various stages, for the earlier stages often possess characters of importance, throwing

much light on the real affinities of the insects, which characters disappear in the half-grown or full-grown larva. The organs of the perfect insects are also receiving much attention from various entomologists who interest themselves in morphology; and two years ago Dr. Enzio Reuter, of Helsingfors, published an elaborate account of the structure of the palpi in butterflies; while in the last part of *Novitates Zoologicae*, the organ of the Tring Museum, Dr. K. Jordan has published a long and interesting article on the antennae of butterflies, dealing especially with the structure of the scales, sense-hairs, setiferous punctures and sense-bristles in the various families of butterflies, and, incidentally, in some moths. As is generally the case in such inquiries, "we learn that an antennal organ or structure is variable in one family, while it is relatively constant in other groups." We have not space to notice Dr. Jordan's remarks on the bearings of his inquiries on the phylogeny and classification of butterflies, for which we must refer our readers to the paper itself.

IN the same part of the *Novitates Zoologicae*, Dr. Jordan replies to some severe criticisms made by the late Prof. Eimer on the views put forward by the Hon. Walter Rothschild and Dr. Jordan on the classification of the *Papilionidae*. We cannot enter into the controversy; but may say that Dr. Jordan holds that Prof. Eimer was himself in error, owing to want of sufficient materials on which to base trustworthy conclusions.

MESSRS. OLIVER AND BOYD, Edinburgh, will, early in 1899, publish a book containing a biographical sketch of the late Mr. James Shaw, Tynron, and selections from his prolific writings on scientific, antiquarian, rural and literary subjects. Two hundred and fifty copies have already been subscribed for, and the material is now being prepared for press by Prof. Robert Wallace, University, Edinburgh, to whom all communications on the subject should be addressed.

A CONSIDERABLE space in the *Journal of Horticulture* for October is occupied by several papers on perfumes, by Mr. F. W. Burbidge. He gives a long list of perfumes and essential oils, and of the plants from which they are obtained, and a copious bibliography of the subject. A description and drawing is also given of the late Mr. A. Smee's apparatus contrived for condensing the perfume from fresh flowers; and reference is made to the antiseptic properties of perfumes, and to their remarkable power, as described by Prof. Tyndall, of absorbing heat from the atmosphere. The burning of perfumes or incense in churches, hospitals, &c., had undoubtedly originally a hygienic purpose. The Rev. G. Henslow gives a paper on the advantages to gardeners of a knowledge of vegetable physiology; and Mr. F. Enock one of his entertaining papers, very well illustrated, on insect blights and blessings. Mr. F. M. Bailey adds three new species of *Nepenthes* to the flora of Queensland, the pitchers of which are figured.

A VOLUME containing reports of experiments on the manuring of oats, hay, turnips, and potatoes, conducted in 1897 on farms in the south-west and centre of Scotland, under the direction of the agricultural department of the Glasgow and West of Scotland Technical College, has just been published.

THE following announcement is made in the *British Journal of Photography*:—"M. Berthiot, the well-known optician of Paris, has constructed a new 'satz' or casket of wide-angle lenses. It contains four single lenses; composed of three elements that have 24, 24, 31 and 39 cm. foci respectively, and can be used as single lenses, or combined they give 12, 16, 16 and 17·5 cm. foci lenses. On the authority of Dr. C. Fabre, the author of the well known *Traité Enclyclopédique de Photographie*, the doubtlets will include an angle of more than 100° without spherical aberration."

THE fourth volume of "Bibliotheca Geographica," edited by the Berlin Gesellschaft für Erdkunde, and prepared by Dr. Otto Baschin, has just appeared. It is a classified catalogue of geographical works published during 1895, the works being arranged alphabetically according to authors. The classification adopted is as follows:—A. General geography: (1) bibliography; (2) methods and instruction; (3) general publications; (4) historical geography; (5) mathematical and astronomical geography, cartography; (6) physical geography; (7) biological geography; (8) anthropo-geography; (9) hints for travellers and observers. B. Special geography: (1) voyages and travels in several continents; (2) Europe; (3) Asia; (4) Africa; (5) Australia and New Zealand; (6) Oceania; (7) America; (8) polar regions; (9) oceans and seas. The publisher of the bibliography is W. H. Kuhl, Berlin.

A USEFUL series of graduated arithmetical examples, worked in full by approved methods, makes up a little volume entitled "How to Work Arithmetic," by Mr. Leonard Norman, published at the Rugby Press. The models appear to have been carefully chosen, and should be of assistance in cultivating neatness of style and uniformity of method in large schools.—The use of sketches in teaching the first rules of arithmetic is shown in the "Picturesque Series" of arithmetical problems published by the National Publishing and Supply Association, Ltd., Reading, for Standards I. to III. of elementary schools. The same publishers issue a "Deductive Series of Arithmetical Problems," by Mr. T. Bowen, based on questions asked by inspectors of elementary schools, and with solutions of leading questions worked in full. We have also received from the National Publishing and Supply Association the second edition of "Quantitative Exercises for Beginners in Chemistry," Parts I. and II., by Mr. A. H. Mitchell. The books are adapted to the requirements of students under the Department of Science and Art in quantitative and qualitative analysis.—The third edition of a "Key to Algebraical Factors, and their application to various Processes in Algebra," by Mr. Dorabji H. Vachha, has been published by Messrs. Longmans, Green, and Co.

A SERIES of experiments on the connection between taste and chemical composition has been carried out by Dr. Kahlenberg, and described by him in the *Bulletin* of the University of Wisconsin. Thirteen persons between twenty and thirty years of age—three being women—a lady of sixty, and a gentleman of sixty-three, served as subjects. The subjects were abstainers from alcohol and tobacco, and were kept in ignorance of the composition of the liquids tasted. The results show that for a substance to affect the taste, it must be soluble in water readily diffusible and capable of reacting chemically with the protoplasm of the terminals of the nerves of taste. The taste of solutions is said to correspond to the modern theory of electrolytic dissociation. Thus a sour taste is attributed to hydrogen ions, which may be detected in a 1/800 normal solution, whilst alkaline taste is due to hydroxyl ions. Chlorine ions have a salty taste, and so in a less degree have bromine and iodine ions. The variation of intensity of taste with atomic weight, here indicated, is said to be observed with positive ions.

THE current number of the *Berichte* contains an account of the re-determination of the density of ozone by Prof. Ladenburg. The ozone was prepared as pure as possible by cooling ozonised oxygen in a tube surrounded by liquid air. Of the 22 cc. of liquid thus obtained, nine-tenths were allowed to evaporate in order to remove the liquid oxygen. In this way 2 to 3 cc. of a blue-black opaque liquid were obtained, and with the gas produced by its evaporation two experiments were made, one to determine the density, the other to determine the percentage of ozone. The density was determined by measuring the velocity of effusion, water being used instead of mercury as the trapping

liquid. The amount of ozone in the gas was determined by means of potassium iodide and sodium thiosulphate. The results gave for ozone a density of 1·456 as compared with 1 for oxygen; the theoretical number being, of course, 1·5. The agreement, considering the difficulty of the experiments, is quite satisfactory. In the course of the observations Prof. Ladenburg found that water at ordinary temperatures and pressures does not dissolve more than one-hundredth of its volume of ozone. In attempting to determine the boiling point of liquid ozone it appeared that this point lay at $-125°$ C., but as soon as the boiling commenced the liquid exploded with great violence and reduced the whole apparatus to powder.

THE additions to the Zoological Society's Gardens during the past week include a Serval (*Felis serval*) from Africa, a Black-footed Penguin (*Spheniscus demersus*) from South Africa, presented by Mr. H. S. H. Cavendish; two Black-backed Jackals (*Canis mesomelas*) from South Africa, presented by Lady De Trafford; a South Albemarle Tortoise (*Testudo vicina*) from South Albemarle Island, Galapagos Group, presented by Captain E. S. Tindall; a Ring-tailed Lemur (*Lemur catta*) from Madagascar, a Garnett's Galago (*Galago garnetti*) from East Africa, a —— Kangaroo (*Dorcopsis*, sp. inc.) from New Guinea, an Orange-winged Amazon (*Chrysotis amazonica*) from South America, deposited; two Spur-winged Geese (*Plectropterus gambensis*), two —— Fruit Pigeons (*Phalacrotreron abyssinica*) from West Africa, two Bar-tailed Godwits (*Limosa lapponica*), European, purchased; a Bennett's Wallaby (*Macropus bennetti*), two Squirrel-like Phalangers (*Petaurus sciureus*), born in the Gardens; six Glossy Ibises (*Plegadis falcinellus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE LEONIDS.—During the present week, if we are favoured with fine weather, the Leonid swarm or swarms of meteorites should be very conspicuous, assuming they have not decreased very considerably in number since the year 1865. That a great number of observers will be on the watch for them, there is little doubt, and photography will most probably be extensively used for obtaining records in addition to the naked eye It may be well here to sum up some of the important features which must be noted when observing these moving strangers, and we cannot do better than enumerate those given by Mr. Denning in his interesting article (*Observatory*, 1897) on this great meteor swarm. Thus, the observer should record the exact time of maximum abundance, the number of meteors per minute, the position of the centre of radiation, the area of this radiant if diffuse, and the duration of the shower's chief activity. Further, their relative magnitudes, duration of their visible flights, colours, and the apparent paths of the brighter meteors should be noted. Many other peculiarities which the observer may remark, such as shape of nuclei and apparent diameters of bolides (if there be any), description of curved paths, broken streaks, and duration of streaks with direction of their drift, should be accurately recorded. A convenient form of table for entering such data could be made with the following headlines:—Date, Greenwich Mean Time, Magnitude, Observed path (from R.A., Dec. to R.A., Dec.), Length of trail, and Notes.

It will be of interest to inquire whether the shower is divided into three parts, as Mr. Marsh has suggested. The following is the predicted times for these groups when they will be centrally passed by the earth:—

	Preceding.		Central.		Following.	
		h.		h.		h.
1897 ...	Nov. 13	9·25	Nov. 14	0	Nov. 14	15
1898 ...	,,	15·75	,,	6·5	,,	21·5
1899 .	,,	22·25	,,	13	,,	4

As there will be practically no moon to interfere with the observations this year, every opportunity ought to be taken to obtain a good record. Next year at the same period the moon will be nearly full and visible the whole night, and this will undoubtedly interfere with observations, in spite of the fact that the number of meteors reaches its maximum.

The accompanying chart, which is a reproduction of that published by Prof. W. H. Pickering in his account of the last year's observations at Harvard, shows the position of the radiant point in Leo and the neighbouring constellations.

Further information concerning the probable appearance of this swarm of meteors will be found in the interesting article contributed by our well-known authority on this subject, Mr. Denning, in the present issue.

COMET BROOKS.—This comet is rapidly decreasing its declination and becoming fainter. The following ephemeris is based on the elements of Ristenpart and Muller.

1898.	R.A. (app.)	Decl. (app.)	Br.
	h. m. s.	° '	
Nov. 11	17 53 1	+ 7 39·6	0·6
13	17 57 14	4 50·4	
15	18 0 56	+ 2 16·3	0·5

The comet is still in the constellation of Ophiuchus, and on the 15th will lie in the prolongation of a line joining κ and β Ophiuchi at a distance from β of about one-third of that between these stars.

STARS WITH GREAT VELOCITIES IN THE LINE OF SIGHT.—Prof. W. W. Campbell, who is making spectrographic determinations of stellar motions, has found evidences of large velocities in several of the stars he has examined. η Cephei is one of the stars he mentions (*Astrophysical Journal*, vol. viii. No. 3), and the mean velocity deduced on five different occasions from a discussion of 136 lines in the spectra amounts to $-86·8$ kilometres per second; this when corrected for solar motion reduces to $-74·1$ kilometres per second. The results of Belopolsky for the brighter component of ζ Herculis (*Astr. Nachr.*, vol. 133, p 257–262) have also been corroborated, the corrected velocity amounting to $-53·9$ kilometres per second. It may be remembered that Prof. Keeler found for the planetary nebula G.C. 4373 as a result from six nights of measurement, a velocity of $-64·7$ kilometres per second.

η Pegasi seems to have a very variable velocity, the extreme range observed amounting to 23 kilometres per second. The velocities that Prof. Campbell has obtained up to the present time are:—

	km.		km.
1896 Aug. 27	+ 7·1	1898 Aug. 29	+ 16·5
Sept. 23	+ 5·1	Aug. 30	+ 15·6
1897 July 8	− 6·4	Sept. 4	+ 16·5
Sept. 28	− 2·2		

We are evidently here dealing with a period somewhere about two years in length. Prof. Campbell hopes that if other observers have secured measurements of this star, they will communicate their results to assist him in determining the period.

ON KEEPING MEDUSAE AND OTHER FREE-SWIMMING MARINE ANIMALS ALIVE IN SMALL AQUARIA.

ALTHOUGH many marine animals, more especially those which live between tide-marks, or in shallow water near the shore, can without great difficulty be kept in a healthy state in confinement, this is by no means the case with those invertebrates whose natural habit is to swim freely in the sea, and previous attempts to rear pelagic larvae to the adult stage have only rarely been attended with much success. A method of overcoming some of these difficulties, which should prove of considerable use to marine naturalists, has recently been in use at the Plymouth Laboratory, and is described by Mr. E. T. Browne in the *Journal* of the Marine Biological Association (vol. v. No. 2).

Mr. Browne arrived at the idea of the apparatus as the result of repeated attempts to keep medusae alive in confinement. It was noticed that when recently captured medusae were put into clean sea-water, though they at first swam vigorously about, they invariably became sluggish in the course of a few hours, even if the water were constantly changed, settled to the bottom and finally died. When watching medusae in the sea it was observed that they simply float along with the tide without often pulsating the umbrella. It was therefore thought that if a movement in the water of an aquarium could be obtained, which would keep the medusae constantly floating about independently of their own pulsation, better results might be obtained; and this has proved to be the case. A suitable movement of the water can be conveniently brought about by means of a glass plate made to rise and fall slowly through the water.

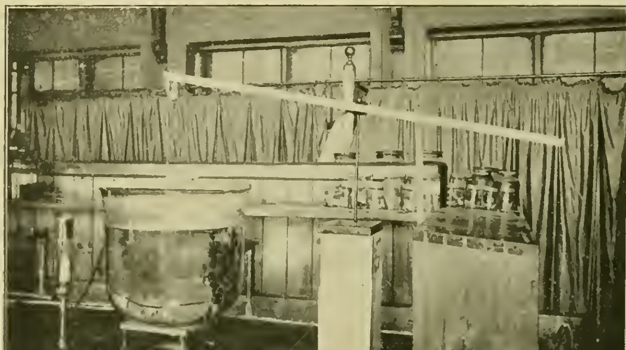


FIG. 1.—Bell-jar with glass plunger.

A motion of this kind can be arranged in many different ways, the apparatus, illustrated in Fig. 1, being the form originally designed by Mr. Browne in conjunction with the Director of the Plymouth Laboratory, which has now been continuously working for a year. The sea water, obtained from the open sea at some distance from shore, is contained in a glass bell-jar of about 10 gallons capacity, provided with a wooden cover made in two halves. A glass plate is suspended in the water by means of a glass rod passing through a hole in its centre, the other end of the rod being attached to one end of a light wooden beam. This beam works on a hinge at the centre, and from its other end a small tin bucket is hung. The bucket is fitted with a self-emptying siphon, and is supplied with a slight stream of water by means of a rubber tube attached to the fresh-water supply. The weights of the bucket and glass plate are so adjusted that the plate moves up and down in the sea-water as the bucket alternately fills and empties. Extra weight is added when required by placing shot in a small bottle hung at one end of the beam. In this way a delicate adjustment can be made, and the plate caused to travel as slowly as is desired. The length of the stroke is regulated by two stops, and a slit in the cover of the bell-jar, through which the glass rod passes, prevents the plate from striking the sides of the jar.

Arrangements have since been made in the laboratory, by which a large number of glass plates, or "plungers" as they have been named, can be worked in a similar way. A modified form of the apparatus, in which the glass plate is replaced by a glass funnel with a small hole in its top, has also been used with advantage. The funnel is fixed so that it is brought out of the water by the upward stroke of the plunger. At each downward stroke it carries with it a funnel-full of air, which escapes by way of the hole, and bubbles through the water.

Amongst the medusae which were successfully kept in the bell-jar were *Phialidium buskianum*, which grew and developed fresh tentacles, *Phialidium cymbaloideum*, which in twenty-five days added five new tentacles and five marginal bulbs, and a species of *Margelis*, which in seventeen days added two new tentacles in each of the four marginal groups, and the oral tentacles twice dichotomously divided. Two medusae of *Cladonema radiatum* were placed in the same bell-jar in the summer of 1897, and in the following spring several colonies of the hydroid of this species appeared. During the present summer (1898) these colonies have freely budded off medusae, several hundreds being seen in the bell-jar at one time.

Crustacean, annelid and molluscan larvae were put into the bell-jar from time to time (together with Copepods), as food for the medusae. Many of the larvae, which escaped capture by the medusae, continued to develop and attained the adult form. Amongst these were *Chaetopterus variopedatus* (the tube of an adult worm from an 1897 larva being about four inches long in June 1898). *Capitella capitata*, *Polynoe* sp., *Nika edulis*, *Portunus* sp., as well as small Gasteropods, Hermit-crabs, and Barnacles. Colonies of hydroids were also found to flourish well when kept in similar aquaria and plentifully supplied with Copepods, which they capture and devour in large numbers. E. J. A.

PHYSICS AT THE AMERICAN ASSOCIATION.

THE Physics Section (Section B) of the American Association was organised with Vice-President Prof. F. P. Whitman in the chair. His vice-presidential address, on colour vision, printed in the issue of *Science* for September 9, was well received, and constitutes a valuable *résumé* of the subject.

The programme of the Section included titles of fifty papers, of which forty were read. Many of these papers were of a very high order, and almost every one of them was creditable and interesting. Brief abstracts of some of them are subjoined.

"A redetermination of the ampere," undertaken, under a grant from the Association, by Prof. G. W. Patterson and Mr. Karl E. Guthe, of Ann Arbor. This work, for which an accuracy of about one part in 8000 is claimed, gives 0·0011192 grammes for the electro-chemical equivalent of silver, and reconciles almost exactly the mechanical equivalent of heat as obtained by electrical methods with Prof. Rowland's corrected

value. An electro-dynamometer of the Weber type was used for measuring current, and the torque due to the current was balanced by the torsion of a phosphor-bronze wire. This wire was standardised by studying its torsional vibrations in a vacuum when carrying a mass of known moment of inertia, and precautions were taken to eliminate the effects of elastic lag.

Experiments bearing upon the "velocity of light in a magnetic field," which were undertaken under a grant from the Association, were reported by Profs. E. V. Morby, H. T. Eddy and D. C. Miller. Their conclusion is that the velocity of light in carbon bisulphide is not altered by one part in a hundred million by a magnetic field of such an intensity as to turn the plane of polarisation through 180° in a path of 65 cm.

"A new gas" was described by Mr. Charles F. Brush. While searching for evidence of the absorption of hydrogen by glass, Mr. Brush discovered that pulverised glass gives off, when heated at a low pressure, a gas whose thermal conductivity at a pressure of a few millionths of an atmosphere is about a hundred times that of hydrogen. This gas was obtained from many other substances, and also by diffusing air through a porous porcelain plug. The kinetic theory indicates that the heat conductivity of a gas is proportional to the reciprocal of the square root of its density. Assuming this relation to hold, this new gas must have a molecular weight of only 0·0002, and a molecular velocity 100 times that of hydrogen.

"On the relative brightness of pigments by oblique vision," by Prof. F. P. Whitman. Prof. Whitman used the flicker photometer, and found that the brightness at the red end of the spectrum decreases as the vision becomes more oblique, while the opposite is true (but to a less extent) at the violet end. The brightness of yellow-green is nearly independent of the angle.

"A geometrical method for investigating diffraction by a circular aperture," by Prof. A. G. Webster. Prof. Webster plots the definite integral involved in this case, and obtains a curve similar to Cornu's spiral, but having cusps like a ratchet.

N. ERNEST DORSEY.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The one hundred and ninety-second meeting of the Oxford University Junior Scientific Club was held on Wednesday, October 26. After private business, Prof. Sollas read a paper on "Funafuti; a study of a Coral Reef." Mr. E. Gurney (New College) then read a paper on "The Birds of the Westman Islands"; in this he also touched upon the characteristic beliefs of the Icelanders, who make their living by catching the birds.

The one hundred and ninety-third meeting of the Club was held on Friday, November 4. After private business, which included the election of twenty-three new members, Dr. Gustav Mann read his paper on "The Origin of Life." Mr. E. S. Goodrich (Merton) briefly explained a model, devised by an American painter, to illustrate the theory of protective coloration in birds, after which the meeting ended. The officers for this term are:—President, Mr. F. P. Nunneley (B.N.C.); Biological Secretary, Mr. E. Gurney (New College); Chemical Secretary, Mr. H. B. Hartley (Balliol); Treasurer, Mr. W. E. Blackall; Editor, Mr. H. E. Stapleton (St. John's); Committee, Mr. F. Soddy (Merton), Mr. A. Angel (Christ Church), Rev. G. D. Allen.

CAMBRIDGE.—At St. John's College, on November 7, the following graduates of the College were elected to fellowships: R. C. Maclaurin, twelfth wrangler 1895, first division of first class Mathematical Tripos, Part II. 1896, bracketed second Smith's Prizeman 1897, Macmahon Law Student 1898; V. H. Blackman, first class Natural Sciences Tripos 1894–95, Hutchinson Research Student 1897, botanical assistant in the British Museum.

At the biennial election of eight members of the Council of the Senate held on November 7, the following were the successful candidates: The Master of Christ's and the Master of Emmanuel, as heads of Colleges; Prof. Ewing, F.R.S., and Prof. Forsyth, F.R.S., as professors; and Dr. Donald MacAlister, Mr. R. T. Wright, Mr. F. Whitting, and Mr. A. W. W. Dale as members of the Senate.

MR. THOMAS REID, of Dundee, has been appointed to the post of Head Teacher of the Engineering Department of the Birmingham Municipal Technical School.

MR. SWALE VINCENT has been elected to the Sharpey Physiological Scholarship (150*l*. per annum) at University College, London. This scholarship carries with it the post of chief assistant in the Physiological Laboratory.—Mr. D. J. Armour has been appointed to the vacant demonstratorship in Anatomy.

AT a meeting of the Council of University College, Liverpool, last week, donations to the amount of 13,000*l*. for the Medical School Building fund from the Right Hon. the Earl of Derby, Mrs. George Holt and Miss Emma Holt, Mr. R. Brocklebank, and Mr. J. Rankine were announced, and a Committee was appointed to prepare plans. The Council hope for further contributions to enable them to put the work in hand without delay.

THE Technical Instruction Committee of the County Borough of Plymouth have passed the following resolution with reference to the Secondary Education Bill introduced into the House of Commons by Colonel Lockwood in June last:—"That this Committee, while generally approving of the introduction of a Bill dealing with this most important subject, is of opinion (1) that it would be prejudicial to the best interests of higher education if secondary were separated from technical education. (2) Also that the multiplication of local authorities for educational purposes is undesirable. (3) That the funds at the disposal of Technical Education Committees are already inadequate for the purposes to which they are assigned, and that it would be impossible to devote any part of the present income to aid secondary education. (4) That the funds which Parliament at present votes for the special encouragement of science and art ought not to be diverted to cover the whole field of secondary education.

THE Calendar for the eighteenth session (1898–9) of the University College, Nottingham, has been received. The College appears to offer every inducement to students to follow systematic courses of study. Day courses of instruction are specially arranged for boys who have just left school and intend to follow the engineering profession in one of its branches. The course of instruction in architecture has been arranged in conjunction with the Nottingham Architectural Society and the School of Art; and the commercial course has been arranged in conjunction with the Nottingham Chamber of Commerce. The associate course in chemistry requires work in the College practically the whole time for three sessions. All chemistry students are strongly advised to continue their studies during a fourth year, so that they may undertake some original investigation and work at the higher branches of the subject. The courses in technical and practical physics, engineering, natural sciences, and agriculture provide for thorough work in these subjects.

IN general (says the *New York Nation*) the Prussian Government, in deciding the salary of a teacher, makes the sum depend to a great extent on the personality and reputation of the individual. A special law regulates the inequality resulting from the difference in the lecture fees received by the various professors—these lecture fees in all the German universities being an income in addition to the regular salary—by decreeing that in Berlin the full professor can receive annually only one-half of these in case they exceed the sum of 4500 marks, and in the provinces 3000; the other half being taken by the State for the benefit of other teachers not blessed with large salaries or fees. In the Würtemberg University of Tübingen, a three-class system of normal salaries is in vogue for the full professors, based on the years of service. The minimum salary is 4030 marks. The assistant professor begins with 2020. A special fund of nearly 150,000 marks is at the disposal of the Government for special salaries in special cases. In the two universities of Baden, Heidelberg and Freiburg, the average salary of the ordinarius is 6955 marks, with additional sums in special cases. The assistant professors draw salaries varying from 1820 to 5220 marks. The Imperial University at Strassburg and the Saxon at Leipzig pay good salaries, but the sums are not mentioned; while the Hessian Institution at Giessen pays its full professors 4300, and its assistants or associates 3250, with an increase until after twenty-five years of service the maximum sums of 6300 and 5250 are reached. In Rostock, the smallest of the German universities, the salaries of the full professors run from 4500 to 5850 marks; the assistant professor begins with 2400. In Jena the lowest sums are paid, the full professors receiving 300 less than is paid even at Rostock.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, October.—The number opens with an account of the fifth summer meeting of the Society, which was held at the Massachusetts Institute of Technology, Boston. As on former occasions, the Society was affiliated with Section A of the American Association for the Advancement of Science. There was a large attendance of members, and at the three sessions which were held twenty-five papers were communicated. Short abstracts of papers by Messrs. Blake, Chessin, Lovett, Baker, Hall, Moore, Conant, Boyd, Stecker, Dickson, Stabler and Martin are given. The journals in which these papers will appear are indicated. Note on the generalisation of Poincaré and Goursat's proof of a theorem of Weierstrass's, by Prof. Osgood, gives an interesting sketch of the theorem, accompanied by full references to original memoirs.—The same author supplies a supplementary note on a single-valued function with a natural boundary, whose inverse is also single-valued. This is supplementary to a paper in the June *Bulletin*, and states the writer's indebtedness for a simple proof of his principal theorem to Prof. Hurwitz.—Prof. Chessin contributes a note on the periodic developments of the equation of the centre and of the logarithms of the radius vector.—The theorems of oscillation of Sturm and Klein is a third paper on the subject, by Prof. Bôcher. Its object is to extend the results previously established to some cases in which the coefficients of the differential equation (discussed in the preceding papers) are no longer continuous throughout the intervals considered in the investigation. The article occupies pp. 22–43. There are numerous vacation notes, and a long list of new publications. It is worth noticing that the Society has appointed a Committee to consider the question of securing improved facilities for the publication of original mathematical papers (in the States). On p. 48 it should be Prof. Price has resigned the Sadleian Professorship (not Sadlerian, which is a Cambridge professorship).

Symons's Monthly Meteorological Magazine, October.—Heat and drought in September 1898. Reference to the regular table of rainfall and temperature at fifty stations shows that the month was remarkably dry over the whole of England and Wales. At twenty-one of the stations the rainfall was less than half the average, and nine of them show a deficiency of 75 per cent. The deficiency is most marked in the east and north-east of England, where the falls were generally about a quarter of an inch. September 1895 was very dry; September 1898 yielded a larger number of both absolute and partial droughts, but a smaller number of stations with less than half the average fall. To illustrate the distribution of temperature during the month, a table of shade maxima at twenty-five stations is given, for September 3–9 and 14–17. On all these days there are numerous entries above 80°, while on the 8th there are eleven records of 90° and upwards. Although the absolute maximum at Camden Square in 1898 (91°·2) is unprecedented, and no other September during the last forty years has had so many days above 85°, yet in 1865 there were two more days above 80°.—Results of meteorological observations for September at Camden Square for forty years, 1858–97. The average rainfall is 2·39 inches; the year 1898 had only ·33 inch, being the smallest September fall since 1858. The mean temperature in September for the forty years is 57°·7. The mean for 1898 was 61°·6, being an excess of 3°·9 from the normal; there is only one instance of a higher mean, viz. 63°·6, in the year 1865.

Wiedemann's Annalen der Physik und Chemie, No. 9.—Electric currents produced by Röntgen rays, by A. Winkelmann. Like Perrin, the author succeeded in obtaining differences of potential between two different metals under the influence of x-rays, and also a steady current of about 6×10^{-9} amperes in a circuit containing two such metals. He calculates an inferior limit for the ratio of the number of ionised molecules of air traversed by x-rays to the total number of molecules, and finds it to be $4 \cdot 6 \times 10^{-13}$.—Magnetic hysteresis, by F. Niethammer. The loss of energy in alternate-current hysteresis is greater than in magnetostatic hysteresis. It is nearly the same for sinusoidal and for flat curves, but less for pointed curves, for the same maximum induction.—Reflection of kathode rays, by H. Starke. The rays enter a spherical vessel from a side tube, and are reflected by a metallic mirror mounted in the centre and movable by a handle outside. After reflection, the rays are caught in another side tube containing an electrode leading to a galvanometer. The galvanometer shows the same deflection within wide limits of the orientation of the mirror. Hence the deflection is diffuse, the particles being so small that even a highly polished surface is rough to them. The current is greatly increased by insulating the mirror instead of connecting it to earth. The denser metals have the greater reflective power.—Disintegration of incandescent platinum and palladium wires, by W. Stewart. The disintegration of wires rendered incandescent by an electric current gradually decreases as time goes on, but is unaffected by the presence or absence of moisture in the air. When the air is exhausted, the disintegration of platinum diminishes, while that of palladium increases. Platinum is not disintegrated in hydrogen.—Causes of the changes of resistance discovered by Branly, by D. van Gulik. Branly's view that the conductivity of powders acquired under the influence of electric radiation is due to a modification of the dielectric surrounding them is untenable, as experiments with minute terminals under the microscope prove the correctness of Lodge's view that the conductivity is due to mechanical contact.—Observations concerning coherers, by E. Dorn. To be effective, metallic powders should be somewhat easily oxidised, and should be exposed to the air so as to acquire a coating of oxide. Good results are obtained with iron and copper, but not with the noble metals.—A supposed unknown constituent of the atmosphere, by O. Neovius. The author finds a number of lines which are identical in the nitrogen spectrum and the blue argon spectrum, and may be due to an unknown gas occurring as an impurity in both. These lines show only a single coincidence with those of crypton, at 4736.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, October 28.—Mr. Shelford Bidwell, F.R.S., President, in the chair.—A paper was read by Mr. W. R. Pidgeon on an influence machine. The machine, which was exhibited, consists of a pair of glass discs, rotating in opposite directions upon a spindle. They are partially covered on one face with narrow radial sectors of tin-foil, each provided with a small brass knob. This face of the disc, including its sectors, is then coated with insulating wax, leaving only the knobs projecting through the wax. Two earthing-brushes pass through two insulated fixed inductors, and support them. The inductors are kept charged by exploring-points connected to each, and placed so as to collect electricity from the revolving discs. By means of brushes, the sectors on each of the discs are successively earthed at the moment they pass the fixed inductors, *i.e.* at the moment that their capacity is a maximum; and they are made to deliver up their charge to the main collecting brushes at the moment when they are electrically farthest from the inductors, *i.e.* when their capacity is a minimum. Hence, if there is no loss of electricity in the process, the potential at the collecting brushes is proportionately high. Each sector of a particular disc, as it moves away from its inductor with rising potential, induces a corresponding potential on the sectors opposed to it on the second disc; this action is cumulative. The thick coating of wax restricts leakage to the small area of the contact knobs, so that surface effects of dirt and moisture are minimised. Captain J. H. Thomson, R.A., said that, apart from its electrical merits, the machine possessed advantages in mechanical construction. He thought there was still room for improvement in this respect. The counter-shaft should be done away with, and ball-bearings should be introduced. The inductor was a distinct improvement; he thought the efficiency might be increased by adding other inductors. Platinum-iridium was the best material for brushes of such machines. Prof. Ayrton asked what efficiency was obtained with modern influence machines, in general. Captain Thomson had found that when running a machine by a motor, about 80 per cent. of the power was wasted in mechanical friction; of the remaining 20 per cent. a great deal was lost as electrical leakage. Prof. S. P. Thompson thought it had been pointed out by Mr. Wimshurst that influence machines did not work well unless there were at least two thicknesses of glass between the inducing and induced conductors. That was why Mr. Wimshurst put his sectors on the outer faces of the glass discs. Mr. Pidgeon had departed from this. The advantage of the narrow spacing of the sectors was not very apparent. Mr. Wimshurst (abstract of communication): Waxing the discs reduces leakage, and increases the output; the wax-coating virtually doubles the number of plates. Inductors contribute a further increase to the output. In 1883 Mr. Wimshurst tried thick coatings of shellac, and also, duplicating the glass, with in

some cases sectors upon the second glass to increase the capacity. The output was increased, but the construction lost simplicity. The indifference of Mr. Pidgeon's machine to dirt and dust was a most valuable result. Mr. Pidgeon, in reply, showed a set of secondary inductors such as Captain Thomson had just proposed. They improved the output by about 15 per cent., but they were troublesome to keep in order, for they increased the tendency to "reverse."—Dr. S. P. Thompson then repeated an experiment discovered by Prof. Righi, on a magneto-optic phenomenon. It was originally described in *Roma, R. Accad. Lincei, Atti* 7, *ser.* 5, 1898. A substance absorptive of light is submitted to a powerful magnetic field between the pole-pieces of an electro-magnet. The pole-pieces are drilled so that a beam of light from an arc-lamp can traverse the gap *along* the magnetic lines. A polarising prism is placed between the arc-lamp and the electro-magnet. After having passed through the magnetising apparatus, the beam thus polarised is examined by an analyser. The analyser must be turned to "extinction" before the magnetising current is turned on. If this is done, brightness is restored at the analyser as soon as the magnetic field is established. The substance absorbing the light in the gap may be nitric oxide fumes, or an ordinary spirit-lamp sodium flame. The second effect to be noticed is that when the emergent beam is examined, there is a splitting of the lines. Righi explains this by supposing that when light of frequency n is brought into a magnetic field and passed *along* the lines of the field, it is split up into two sets of circular waves, a right-handed and a left-handed set, one of which sets is accelerated and the other retarded. There are now two frequencies n_1, n_2, one a little higher and the other a little lower than n. But since the analyser is adjusted to extinguish n, there is brightness for n_1, n_2. Normally, nitric oxide absorbs green, and red is observed; but when the magnetic field is set up, blue-green light is seen at the analyser; for there are now two different kinds of light being absorbed, one of higher and one of lower frequency than the normal, and what is observed is the complementary spectrum. Again, if a tube of sodium is warmed to a point far short of that which would cause it to emit visible rays, and the vapour is passed into the magnet gap, at the moment when the magnetic field is set up the D line becomes visible in the observing spectroscope, *i.e.* the emission spectrum is obtained of a substance which is not actually emitting light. Mr. Blakesley said that no doubt the analyser was used at the position of extinction for convenience merely. In other positions the eye would be overwhelmed with light.—Mr. Albert Campbell then read a paper on the magnetic fluxes in meters and other electrical instruments. He has recently undertaken the measurement of the magnetic fluxes and fields in certain instruments, to determine the order of magnitude of the flux density. In other cases the *total* flux is measured; and in the tests on meters, the power lost in the various parts of the instruments is determined. For the measurement of B, the ordinary ballistic-galvanometer method is employed, with an exploring-coil. But, for alternating fluxes, two special methods are adopted, in the first of which the exploring-coil is in series with a heating-coil associated with a thermopile; in the second, a telephone is connected in series with the search-coil and a potentiometer resistance strip. A constant current is sent through the strip from the main alternate-current circuit supplying the meter or other apparatus; the telephone and search-coil therefore forms a shunt to that circuit at the strip. The search-coil is put into position in the field to be tested, and the strip is then adjusted to give silence in the telephone. All these methods are described in detail in the paper, and very important deductions are made, especially as regards the influence of the earth's field on instruments generally assumed to be independent of the earth's H. In a few cases, diagrams are given of the fluxes in magnets, showing exactly what proportion of the total flux is effective at the gap. Dr. S. P. Thompson suggested that as the paper was of great significance to all who were interested in the design of electric meters and other measuring instruments involving a knowledge of magnetic fluxes and their variation, an opportunity should be given for a full discussion.—The President proposed votes of thanks, and adjourned the discussion of Mr. Campbell's paper to the next meeting on November 11.

PARIS.

Academy of Sciences, October 31.—M. Wolf in the chair.—Remarks on rotatory magnetic polarisation, and anomalous dispersion, by M. Henri Becquerel. Remarks concerning the experiments of MM. Macaluso and Corbino. A bundle of polarised white light traverses the pierced armature of a strong electro-magnet, and is analysed by a spectroscope after passing through a sodium flame placed in the field. The absorption bands under these conditions are seen when the current is passing to be bordered by a series of bright dark bands, which are displaced on rotating the analysing nicol.—Peculiarities relating to the innervation and general physiological properties of the nerves of the *sphincter ani*, by MM. S. Arloing and Edouard Chantre.—On divergent series and functions defined by a Taylor's series, by M. Le Roy.—A property of a first integral of the equations of dynamics of two variables with homogeneous potential, by MM. W. Ebert and J. Perchot.—On the ratio of the two specific heats of gases, and its variation with temperature, by M. A. Leduc. From the formulae developed in previous papers the author concludes that γ, the value for the ratio of the two specific heats of air, varies slightly with the temperature, the ratio γ_0/γ_{100} being about 1·0006. The variation is much more rapid with carbon dioxide, for which γ_0/γ_{100} is 1·028. From the experiments of Wüllner, the values of γ_0 are calculated for several gases.—New apparatus for the measurement of luminosity, by M. Onimus. The apparatus described permits of the comparison of the light intensities of two days, or of one country with another. The method adopted is a photographic one, the tint taken up by a standard sensitised paper under fixed conditions being compared with a tintometer prepared by superposing pellicles of slightly tinted collodion; the deepest tint, No. 24, being composed of 24 pellicles of collodion. The apparatus is extremely simple, and can be used without any special knowledge of photography, the ferro-prussiate paper used requiring only washing with water after exposure.—Action of phenylhydrazine upon chloranilic acid, by M. A. Descomps. The result of the reaction is a well-crystallised substance of the composition $C_6Cl_2O_2$,

$$(OH.C_6H_5.NH.NH_2)_2,$$

analogous to the body obtained by MM. Baeyer and Kochendoerfer by the interaction of phenylhydrazine and phloroglucinol.—On the presence of a soluble proteo-hydrolytic ferment in mushrooms, by MM. Em. Bourquelot and H. Hérissey. A solution of the ferment was obtained by triturating the fungi *Amanita muscaria* and *Clitocybe nebularis* with sand and chloroform water, and this was allowed to act upon milk, specially freed from fat. The action of the ferment is analogous to, if not identical with, trypsine.—On the influence of temperature on the determination of sex, by M. Marin Molliard. Experiments carried out on the development of *Mercurialis annua* at varying temperatures showed that heat favours, in this case, the production of female individuals.—Characters of the latent life of bulbs and tubers, by M. Leclerc du Sablon.—The limurites in contact with the granitic rocks of the Hautes-Pyrenees, by M. A. Lacroix. These rocks are characterised by the existence of a violet axinite, which sometimes forms nearly the whole rock mass, but is more often accompanied by pyroxene, quartz, albite, and other minerals.—Experimental study of subterranean sedimentation, by M. Stanislas Meunier.—On the secondary formations of the south of the Montagne-Noire, by M. René Nicklès.—The absorption of mercury by leucocytes, by M. Henri Stassano. The leucocytes of the blood of dogs, into whose veins minute quantities of mercury perchloride had been injected, showed, after careful separation, the presence of a perceptible amount of mercury. The experiments show clearly that the leucocytes are the exclusive agents of transportation and absorption of mercurial compounds in the circulation.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iii. for 1898, contains the following memoirs communicated to the Society:—

May 14.—G. Kümmell: The climatological data of Göttingen for the years 1887–1896.

March 19.—E. Wiechert: Experimental researches on the velocity and magnetic deviability of the kathode-rays.

July 9.—W. Voigt: On the light which penetrates the second medium in so-called "total" reflexion.—A Hurwitz: On the composition of quadratic forms of any number of variables.—E. Timerding: The Reyeian geometry of the *continua* of projective ground-forms.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 10.

MATHEMATICAL SOCIETY, at 8.—Some Secondary Needs and Opportunities of English Mathematicians: Presidential Address.—The Structure of certain Linear Groups with Quadratic Invariants: Dr. L. E. Dickson.—Multiform Solutions of certain Differential Equations of Physical Mathematics and their Applications: H. S. Carslaw.—A Discovery in the Theory of Compound Partitions: Major Macmahon, R.A., F.R.S.—On Groups of Order $p^a q^\beta$: Prof. Burnside, F.R.S.—On the Null Spaces of a One System and its Associated Complexes: W. H. Young.—On the Functions Y and Z which satisfy the Identity

$$4(x^p - 1)/(x - 1) = Y^2 \pm pZ^2:$$

Prof. L. J. Rogers.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Rotatory Converters: Prof Silvanus P. Thompson, F.R.S.

FRIDAY, NOVEMBER 11.

ROYAL ASTRONOMICAL SOCIETY, at 8.—The Development of $\left[\frac{r}{a}\right]^n$ sin cos mw: R T. A. Innes—Remarks on Dr. Gill's Paper in the *Monthly Notices* for June 1898: A. A. Rambaut.—Note on Mr Pogson's Manuscripts relating to his proposed Atlas of Variable Stars: Rev. J. G. Hagen.—(1) On the South Temperate Current of Jupiter; (2) Nomenclature of the Chief Surface Currents of Jupiter: A. Stanley Williams.—(1) On a New Instrument for Measuring Astrophotographic Plates; (2) On a Method of obtaining Perfectly Circular Dots unaffected by Phase, and their Employment for Determining the Pivot Errors of the Cape Transit Circle: David Gill.—On some Photographs of the Moon, Comets, Meteors, and the Milky Way, and on the Exterior Nebulosities of the Pleiades: E. E. Barnard.—(1) Mean Areas and Heliographic Latitudes of Sun-spots in the Year 1897, deduced from Photographs taken at Greenwich, at Dehra Dûn (India), and in Mauritius; (2) Observations of Planet 433 (1898 DQ) with the 30-inch Reflector of the Thompson Equatorial: Royal Observatory, Greenwich.——*Papers promised*: Brief Account of the New Photographic Telescope at Cambridge Observatory: Sir R. S. Ball.—(1) Approximate Ephemeris of the Leonids; (2) Forecast of the Time of the Leonid Shower of 1898; (3) On the Presence of Helium in the Earth's Atmosphere: G. Johnstone Stoney.

PHYSICAL SOCIETY, at 5.—Discussion on Mr. A. Campbell's Paper on the Magnetic Fluxes in Meters and other Electrical Instruments, to be opened by Prof. W. E. Ayrton, F.R.S.—On the Propagation of Damped Electrical Oscillations along Parallel Wires: Prof. W. B. Morton.—On the Properties of Liquid Mixtures: R. A. Lehfeldt.

MALACOLOGICAL SOCIETY, at 8.—A Revision of the Pliocene Non-Marine Mollusca of England: A. S. Kennard and B. B. Woodward.—Description of Two New Species of *Trochidae* from the Commander Islands: Edgar A. Smith.—Description of a New Species of *Tridacna*: G. B. Sowerby.—On some Supposed New Species of Land Mollusca from the Moluccas: H Fulton.

MONDAY, NOVEMBER 14.

IMPERIAL INSTITUTE, at 8.30.—Trinidad, with Special Reference to the Recent Hurricane: H. Caracciolo.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—A British Antarctic Expedition: Addresses by the President and others.

TUESDAY, NOVEMBER 15.

ZOOLOGICAL SOCIETY, at 8.30.—A Revision of the Moths of the Subfamily *Pyraustinae* and Family *Pyralidae*, Part I.: Sir George Hampson, Bart.—List of Mammals obtained by Mr. R. McD. Hawker during a Recent Expedition to Somaliland: W. E. de Winton.—On Mammals collected by Mr. J. D. La Touche at Kuatun, N.W. Fokien: Oldfield Thomas.—Revision of the Genera and Species of Fishes of the Family *Mormyridae*: Mr. Boulenger.

MINERALOGICAL SOCIETY, at 8.—Anniversary Meeting.—Election of Officers and Council.—Plagionite, Heteromorphite, and Semseyite as Members of a Natural Group of Minerals: L. J. Spencer; with Chemical Analyses by G. T. Prior.—Petrographical Notes on Rock Specimens collected during the Ross Antarctic Expedition of 1839–43: G. T. Prior.—Mineralogical Notes from the Oxford University Laboratory (Communicated): Prof Miers, F.R.S.—Note on the Occurrence of Riebeckite in Trachytic Rocks from Abyssinia: G. T. Prior.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Electrical Transmission of Power in Mining: William Beedie Esson.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—On Rapid Dry Plates for Process Work: Combined Screen and Colour Negatives for Three-Colour Printing: A. A. K. Tallent.—On the Melting and Setting Points of Gelatine Solutions, and their Modification: R. Child Bayley.

WEDNESDAY, NOVEMBER 16.

SOCIETY OF ARTS, at 8.—Opening Address by Sir J. Wolfe Barry, K.C.B., F.R.S., on the Internal Traffic of London.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Report on Experiments upon the Exposure of Anemometers at Different Elevations: The Wind Force Committee.—Comparison of Estimated Wind Force with that given by Anemometers: Captain D. Wilson-Barker.—The Tornado at Camberwell, October 29, 1898: William Marriott.

ROYAL MICROSCOPICAL SOCIETY, at 7.30.—Exhibition of Thum's Slides of Diatoms in High Refractive Media.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 17.

ROYAL SOCIETY, at 4.30.

LINNEAN SOCIETY, at 8.—On some Spiders from Chili and Peru: F. O. Pickard Cambridge.—The Botanical Results of a Journey into the Interior of Western Australia: Spencer Moore.

CHEMICAL SOCIETY, at 8.—Preparation of Hyponitrite from Nitrite through Oxyamidosulphonate: Dr. E. Divers, F.R.S., and T. Haga.—(1) Absorption of Nitric Oxide in Gas Analysis; (2) Interaction of Nitric Oxide with Silver Nitrate; (3) Preparation of Pure Alkali Nitrites; (4) The Reduction of an Alkali Nitrite by an Alkali Metal; (5) Hyponitrites: their Preparation by Sodium or Potassium and Properties: Dr. E. Divers, F.R.S.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Story of the Cotton Plant: F. Wilkinson (Newnes).—Primer of Geometry: J. Sutherland (Longmans).—Chemistry in Daily Life: Dr. Lassar-Cohn, translated by M. M. P. Muir, 2nd edition (Grevel).—Das Leitvermögen der Elektrolyte: Dr. F. Kohlrausch and Dr. L. Holborn (Leipzig, Teubner).—Comparative Photographic Spectra of Stars to the $3\frac{1}{2}$ Magnitude: F. McClean (Dulau).—Spectra of Southern Stars: F. McClean (Stanford).—Monographia Roccelleorum: O. V. THE ANATOMY OF BIRDS.

The Structure and Classification of Birds. By F. E. Beddard. Pp. xx + 548, illustrated. (London : Longmans, Green, and Co., 1898.)

READERS of the *Zoological Society's Proceedings* may not improbably have been struck by the comparatively small number of papers communicated to the last few issues by the prosector. The present handsomely got-up volume shows, however, that Mr. Beddard has been fully occupied in anatomical investigations, and he is to be congratulated in presenting the results of his labours in such an attractive and well arranged form.

As stated in the preface, the work is not solely based on his own researches, since his two immediate predecessors in office devoted a large amount of time and labour to the study of the anatomy and affinities of birds. Portions of such work have been from time to time published in separate papers ; but a large amount of MS. was left by Prof. Garrod, of which Mr. Beddard has availed himself. It is thus highly satisfactory to have in a combined and handy form the leading results of the united work of three such distinguished bird anatomists as the author and his two predecessors.

Although works on the external characters and classification of birds abound, treatises in English on avian anatomy and morphology are rare ; and the present work therefore fills a distinct gap—and fills it well. Commencing with a purposely brief sketch of the general principles of bird structure, Mr. Beddard devotes the greater part of his volume to the characteristic structural characters of the different groups of birds. To a considerable extent this ground has indeed been covered by Dr. Gadow, but the author has treated the subject in greater detail, and has recorded a number of new facts, many of which are highly important.

The general anatomy of the class is treated in a manner which, while ministering to the wants of the advanced student, can scarcely fail to interest those lovers of birds who desire to know something more than the mere arrangement and colours of the feathers. And especial attention may be directed to the section devoted to the gradually increasing complexity of the folds of the intestine as we pass to the more specialised forms. Here, as elsewhere, an admirable series of illustrations display in the clearest form the various types of structure discussed.

In the osteological section of general anatomy the paragraph devoted to the hyoid (p. 136), if not absolutely incorrect, is certainly very far from clear, and, moreover, does not agree with the explanatory figure on the opposite page. Again, on p. 140 we meet, in a quotation from Dr. Coues, with the word "fadge," which, if correctly printed, certainly stands in need of explanation to ordinary readers. And, although there is no difficulty about their meaning, we must venture to protest against the use of such terms as "schizorhiny" and "holorhiny," in place of schizorhinism and holorhinism.

Turning to the classificatory portion of the subject, the table of contents looks as though the author was starting a missing word competition—without offering a prize to the solver! At the commencement of the table (p. x.) we find the term *Ornithurae* printed in the same vertical line as a series of other names apparently intended to indicate groups of inferior rank ; and at the end, also in the same line, the term *Saururae*, evidently the equivalent in rank to the first. Such a small error in alignment might well be passed over without notice. But immediately below *Ornithurae* occurs the term *Anomologonatae*, followed in the same vertical line by *Passeres* and *Pici*. And on looking down the table we fail to find any group corresponding in rank to this *Anomologonatae*, so that there is not the faintest clue to the number of orders it is intended to embrace. On turning to the page (167) where the *Anomologonatae* are described we likewise fail to discover its antithesis. Neither does the index help us, since terms of higher rank than genera are excluded therefrom ; this being, in our opinion, a decidedly objectionable plan. Almost by chance, we at length succeeded in stumbling on the missing word—to wit, *Homalogonatae*—on p. 165 ; but even when thus found, the reader is apparently left totally in the dark as to the number of ordinal groups thus brigaded together. Another glaring error in the "Contents" cannot be overlooked. By the position and large type in which the item "Reproduction[tive] and Renal Organs" is printed, it is made to include such subjects as myology, osteology, &c.!

In printing the names of ordinal and higher groups in block type, the author is perhaps well advised. But personally we decidedly object to the names of writers being similarly distinguished ; the important point to which attention should be directed being the fact recorded, and not the more or less distinguished individual by whom it was discovered. And here it may be mentioned that authors' names are not always correctly spelt, a superfluous *e* being generally, although not always, intercalated in that of one well-known avian osteologist. Moreover, if we mistake not, full justice has not been done to the labours of the same writer, who contributed the last paper bearing on one of the subjects on which the late Mr. Wray is alone quoted as the latest authority.

Neither is the work quite free from errors of expression. For example, in treating of the *Limicolae* (pp. 326 and 327), we meet with the following passage :—"The type family is that of the *Charadriidae*, which contains the largest number of genera ; the remaining families are not separated from it by very numerous points of difference, and the group as a whole is very near to the gulls, which I only divide as a family." That is to say, a group is allied to a portion of itself!

As regards the serial arrangement of the various orders (of which a large number are adopted), comparatively few remarks will suffice. Some surprise will be experienced in finding the *Accipitres* placed near the end of the series between the extinct *Ichthyornithes* and the modern tinamous, to neither of which they have any affinity. And when we find it stated (p. 469) that the *Ichthyornithes* themselves are probably allied to the stork and plover tribe, it seems strange to find them located between the *Anseres* and the *Accipitres*. Again,

D

when the author himself admits that the nearest relations of the tinamous are the *Struthiones* (*Ratitae*) on the one hand, and the game birds on the other, it seems decidedly strange that the latter group is not placed in juxtaposition.

The mention of *Struthiones* reminds us that the student perusing the table of contents would gain the idea that the group includes only the two extinct families *Aepyornithidae* and *Dinornithidae*, since these two are alone mentioned. On turning to the corresponding text, it will be found that only these two families are referred to by name, from which we draw the inference that Mr. Beddard has allowed his table of contents to be compiled for him. Of course either all or none of the families should have been given.

Reverting to the orders, it may be noted that Mr. Beddard includes the flamingoes (omitted from the table of contents !) in the *Herodiones*, refusing to admit that they have any relationship with the *Anseres*. In this he is fully supported by osteology. In placing the extinct *Hesporornis* next the divers, we are glad to see that he rejects the recently revived heresy of the Ratite affinities of the former. But whether the penguins are well placed between the *Hesperornithes* and the *Steganopodes* may perhaps be open to question. On the other hand, the location of the owls next the parrots, in association with various groups of the old "Picariae," will probably meet with general approbation.

As regards the ancestry of birds, the author, while refusing to reject a dinosaurian affinity, is inclined to admit some kind of relationship with pterodactyles. It is, however, somewhat difficult to understand such a double consanguinity.

In conclusion, attention may be drawn to the remarkable difference displayed by the caeca of different genera of tinamous, as exemplified by the figures on p. 488. The mere record of such differences is, it is true, an addition to knowledge ; but, as has been remarked by Prof. Newton, what we really want to know is the physiological reason for such variations. And until this is ascertained, we are merely wandering aimlessly in the dark.

As an excellent compendium of the present state of our knowledge of bird anatomy, Mr. Beddard's work may be heartily commended. The blemishes by which the present issue is disfigured may, we hope, be removed in a second edition, which ought to be called for at no very distant date.

R. L.

EGYPTIAN MUMMIES IN THE BRITISH MUSEUM.

British Museum. A Guide to the First and Second Egyptian Rooms. Mummies, Mummy-Cases, and other Objects connected with the Funeral Rites of the Ancient Egyptians. By E. A. Wallis Budge, M.A., Litt.D., D.Lit., F.S.A., Keeper of the Egyptian and Assyrian Antiquities. Pp. viii + 92, with 25 plates. (Printed by order of the Trustees, 1898.)

THE national collection of Egyptian antiquities in the British Museum is, speaking generally, the most complete in Europe. Other collections may perhaps excel it in certain classes of antiquities as, for instance, the Louvre in its unique series of Apis stelae discovered by Mariette, or the Berlin Museum in its specimens of sculpture from tombs of the Early Empire. But the collection in the British Museum is the finest representative collection, comprising as it does typical examples of antiquities of most classes and periods. This is nowhere truer than in the two galleries which are set apart for objects connected with the funeral rites of the ancient Egyptians. During the last twenty-five years, and more particularly during the last ten years, the Trustees of the Museum have been steadily increasing their already fine collection of mummies and mummy-cases, so that they are now in possession of a remarkable series ranging over most of the historical period of Egyptian history, from about B.C. 3600 to A.D. 400. Moreover, the work of arranging and cataloguing the collection has kept pace with that of acquisition. During the past eighteen months any visitor to the Egyptian Department might have noticed a small army of workmen setting in place new wall-cases and standard-cases, remounting the mummies and coffins, and, under the direction of the Keeper, arranging them in chronological order. This work has now been brought to an end with the issue of the "Guide to the First and Second Egyptian Rooms" that has just been published by the Trustees.

To give some idea of the scope of the Guide, it may here be stated that the collection exhibited in these two rooms consists of forty-four mummies and eighty coffins and cartonnage-cases, including typical examples of all periods ; wooden figures of *Ptah-Seker-Ȧusȧr*, the triune Egyptian god of the resurrection ; shabti figures of stone, wood, and glazed porcelain, which were placed in the tombs to do the work of the deceased in the nether world ; and sets of Canopic jars, in which the principal intestines of the deceased were placed, after being removed from the body before the process of embalming. The Guide describes the contents of the galleries, case by case, and as these are arranged in chronological order we can examine and compare at leisure the changing fashions and methods of embalming which were practised by the Egyptians during the long course of their history.

In his Introduction, for the benefit of students who are not Egyptologists, Dr. Budge gives a sketch of the principal features of the Egyptian religion, emphasising their belief in a supreme being, *neter*, apart from the *neteru*, the personifications of special powers or natural phenomena. He then sketches the principal views held by the Egyptians with regard to the nature of the gods and the origin of the universe, and this is followed by a descriptive list of the gods mentioned in the "Book of the Dead," and whose names are frequently met with in the main body of the Guide. Passing to the Egyptian idea of a future life, Dr. Budge enumerates the nine parts which were believed to form a man's personality ; the ritual and ceremonies are next referred to which accompanied the deposit of the dead body in the tomb, and which were gradually grouped together by the Egyptian priests into a number of chapters now generally known as the "Book of the Dead." Finally an account of the different methods of mummifying is given, and the tomb is described with its funereal furniture.

Among the mummies belonging to the early period e two of peculiar interest, which we believe are recent ditions to the collection. These are the skeletons of o Egyptian officials, Khati and Ḥeni, which are exoited in the First Egyptian Room in cases E and F ove the rectangular wooden coffins in which they were und. These two skeletons date from about 2600 B.C., d represent a peculiar method of burial, unlike the ual Egyptian custom of mummifying the body. In e case of Khati and Ḥeni the flesh was removed from e bones before burial by means of muriate of soda or tron, and the bones were then treated with bitumen, hich has tinted them a light yellow; they were then apped in linen, a layer of which may be seen in case under Khati's skeleton. Khati's skull is peculiarly eresting on account of the two indentations in the rietal bones; these, Dr. Budge remarks, "must have en made artificially in early childhood because the rface of the bones is not broken." Ḥeni's bones have en articulated, and the skeleton is about 5 feet 6 inches ng; it is a very fine specimen of this method of ummifying as carried on under the eleventh dynasty. is method of mummifying the dead, by treating the nes with bitumen after removing the flesh, goes back any thousands of years, and was probably the earliest ethod of preserving their dead employed by the inbitants of Egypt; for many of the skeletons from ehistoric sites that have been recently found by M. de organ have been treated with bitumen in a similar anner.

Turning to the later portion of the collection, among the ost noteworthy exhibits are three painted cartonnageses of a Graeco-Roman official (Plate xxiii.) and his o wives, one of whom is figured on Plate xxiv. These e fancy are also recent additions to the collection, and e probably the best examples of their kind in Europe. he modelling is good, so that the cases are remarkably e-like and give a good idea of the dress worn at the riod, about 200 A.D.

We have not done more than give a passing reference three or four out of this unique series of mummies d mummy-cases. Beginning in the First Egyptian oom with the mummy-case of Mycerinus, the builder of e fourth pyramid at Gizeh in the fourth millenium B.C., d ending with the wooden coffin of the Greek or Roman dy, who lies with her three children at the end of the econd Egyptian Room, we can trace upon the mummies d their cases the religious beliefs of the ancient gyptians as they developed through a period of some ur thousand years. To the student of religions a comarative study of this nature presents considerable atactions, and he will welcome Dr. Budge's guide, which upplies him with concise though detailed information on very exhibit in the two galleries. The Trustees, with a iew to enhancing the value of the guide for educational urposes, have issued it in two forms, *i.e.* with and without plates; the former is published at the ridiculously w price of one shilling, and the latter at sixpence. aper and printing leave nothing to be desired.

OUR BOOK SHELF.

An Introduction to Practical Physics for Use in Schools. By D. Rintoul, M.A. Pp. xx + 166. (London: Macmillan and Co., Ltd., 1898.)

SO many volumes containing courses of work in practical physics have lately appeared, that it would hardly seem necessary to increase their number. But a critical examination of the present volume is sufficient to afford justification for adding the book to those previously available. The author succeeded Prof. Worthington at Clifton College, and has carried on the work commenced there of making practical physics a subject practicable for junior students. The experiments described are thus not of the kind invented by the arm-chair philosopher—now happily becoming extinct—but those which have stood the test of experience, and have proved to be suitable for the class of students expected to perform them.

The book does not provide a complete course of practical work in physics, but only on some branches of physical measurement. Experiments on mensuration and hydrostatics occupy fifty-four pages, heat is dealt with in fifty-seven pages, and the third part on dynamics fills fifty-three pages. Light, sound, electricity, and magnetism are not touched upon, but presumably they will form the subject of a second volume. There can, however, be no doubt that the subjects included in the present volume are fundamental for students of physics, and form the best basis for future work.

The plan adopted by Mr. Rintoul, and proved by him to be suited to the mental capacity of boys of thirteen or fourteen, is a compromise between the Socratic and didactic methods of teaching. Sufficient explanation is given to enable the young experimenter to proceed with his work intelligently, and to grasp the significance of the results. He is then in a position to understand the effects produced by different conditions; and Mr. Rintoul provides him with many questions upon which he can usefully exercise his mind.

The book is especially suitable for the modern sides of public schools. As a physical laboratory manual for use in schools of this character it can be highly commended.

A Text-book of Special Pathological Anatomy. By Prof. Ernst Ziegler. Translated and edited from the eighth German edition by Donald Macalister, M.A., M.D., and Henry W. Cattell, M.A., M.D. Sections i.-viii., and ix.-xv., in two vols. (London: Macmillan and Co., Ltd., 1897. New York: The Macmillan Company.)

THE first English edition of Ziegler's "Pathological Anatomy" was published in 1884, and at once achieved the success in this country which the original work had already attained in Germany. It is without doubt the best work in pathological anatomy in English. The present edition, translated and edited from the eighth German edition, brings the ever-increasing subject of pathological anatomy up to date, and it may be said at once that the editors have done their work in an excellent and lucid manner. The two volumes under review deal with the pathological changes occurring in particular parts of the body; and with an aspect of the subject which is of great importance to the practitioner, and of great value to the professed pathologist. The latter will find in the work copious references to the literature of each special part of the subject, arranged in a very useful manner. The ordinary medical student will perhaps find the present work (which will be followed by a third volume) too large for his purpose, but for the student for a university degree, and for the working pathologist, Ziegler's "Pathological Anatomy" is a necessity.

Eclipses of the Moon in India. By Robert Sewell, late of her Majesty's Indian Civil Service, Member of the Royal Asiatic Society, &c. Pp. 13; tables lx. London: Swan Sonnenschein and Co., Ltd, 1898.)

THIS work is in fact a continuation and completion of Mr. Sewell's "Indian Calendar," which was noticed in NATURE for July 9, 1896 (vol. liv. p. 219). The principal matter (besides some notes and additions to the Calendar), is a table of the times, durations, and magnitudes of all eclipses of the moon (whether visible or not in India) for the period of sixteen hundred years, from A.D. 300 to A.D. 1900. The times are reduced to the Hindu prime meridian, that of Lairka (Ujjain), the longitude of which is 75° 46′ east of Greenwich, and are reckoned from mean sunrise (taken as 6h. a.m.) at that place. The calculations are founded on Oppolzer's "Canon der Finsternisse"; but another table gives the figures reduced from the *Nautical Almanac* from its commencement in 1767 (or rather 1768, as no eclipse of the moon occurred in the former year), though the figures in the "Canon" are probably more accurate than those in the Almanac before the year 1819 (not 1821), when Burckhardt's lunar tables were first brought into use in the latter. Mr. Sewell has not thought it necessary to mark the magnitude of an eclipse as greater than total, simply affixing to all such the letter "t." He acknowledges the help in the calculations afforded by Saukara Balkrishna Dikshit, formerly Pandit of the Training College, Poona, whose co-operation was so valuable in his work on the "Indian Calendar," and whose death took place early in the present year; and also expresses his thanks for kind advice and assistance given by Prof. Turner (of Oxford) and Mr. Crommelin (of the Royal Observatory, Greenwich). The precautions taken have probably secured that accuracy which is so particularly essential in matters of this kind; here we will merely point out two errors in p. 4 of the Introduction, where "fixtures" is printed instead of "figures," and Burckhardt's name is spelt without a "k," though Mr. Sewell is liberal of that letter in retaining the obsolete method of spelling "Almanack" with one.

W. T. LYNN.

Famous Problems of Elementary Geometry. By Felix Klein. Translated by W. W. Beman and D. E. Smith. Pp. ix + 80. (London: Ginn and Co., 1897.)

OUR mathematical readers who do not read German will be glad to know that they have now before them a translation of a discussion of three famous geometric problems of antiquity, namely, the duplication of the cube, the trisection of an angle, and the quadrature of the circle as seen through modern eyes. This discussion took place at Göttingen at a meeting of the German Association for the Advancement of the Teaching of Mathematics and the Natural Sciences, and was presented by the great German mathematician, Prof. Felix Klein, with the purpose of bringing the study of mathematics in the university and gymnasium into closer connection. Such an important work as this will doubtless be read very widely, and the joint translators have done good service in making this discussion more available by the excellent translation we have before us.

The Evolution of the Aryan. By R. von Ihering. Translated by A. Drucker. Pp. xviii + 412. (London: Sonnenschein and Co., Ltd., 1897.)

MR. A. DRUCKER has given us a translation of an unfinished work by the late Prof. von Ihering. Much of the argument of the book depends on theories which the leaders of linguistic science have now abandoned. Philologers now confess that community of language does not necessarily imply community of race, and Orientalists and other linguists are hopelessly at variance regarding the "Urheimat" of our race; the book, though ignoring all this, contains much wide reading and keen observation. This is apparent in matters relating to Greek, and especially to Roman, civilisation, the author's special province. In some cases a more intimate knowledge of things Indian would have improved his argument. Thus the Pali Bāveru-jātaka, known to students of folk-lore, is a very important and early witness from the Indian side to commerce between India and Babylon. The "corrective stake" (pp. 54, 55) is also illustrated by the punitive heated pillar (*sūrmi*), mentioned by Manu and earlier authorities.

Mr. Drucker's English is free and lucid; one may quite forget that one is reading a German work on science. In the first sentence of his preface, is not "latest Sanskrit and earliest Babylonian" a slip for the reverse expression?

C. B.

First Lessons in Modern Geology. By the late A. H. Green, M.A, F.R.S. Edited by J. F. Blake, M.A. Pp. viii + 208. (Oxford: The Clarendon Press, 1898.)

THE manuscript of this book was left by the late Prof. Green in a somewhat unfinished condition, and the editor was asked to prepare it for the press. The book is described in the preface as being practically a primer, yet in the third lesson, dealing, among other matters, with the constitution of quartz, after the barest statement of the proportion by weight in which silicon and oxygen combine chemically, and the introduction, with no explanation, of the term "atomic weights," we read: "All this the chemist would express shortly by writing for silica SiO_2; Si standing for twenty-eight parts by weight of silicon, O for sixteen parts by weight of oxygen, and the 2 under the O showing that in silica the oxygen is in the proportion of *twice* sixteen. SiO_2 is called the chemical formula for silica." Is this the kind of information to place before a beginner receiving his third lesson in geology? Later on in the same lesson the chemical composition of orthoclase is dealt with in a similar manner. If the beginner himself were consulted, we imagine his third lesson in geology would be his last. Had the editor omitted these little digressions, which cannot be understood by mere reading, the educational value and the interest of the book would have been much enhanced.

First Stage Inorganic Chemistry (Practical). By Frederick Beddow, D.Sc., Ph.D. Pp. viii + 165. (London: W. B. Clive.)

THE course of practical work contained in this volume follows the elementary syllabus of the Science and Art Department's examination in inorganic practical chemistry. The syllabus gives the outlines of a reasonable course of laboratory work: and therefore the present volume, like others constructed upon the same lines, has several good features. After a few introductory experiments in manipulation, and exemplifying characteristic properties of some common substances, the preparation and properties of a number of common elements and compounds are described. Following this are experiments on the action of heat, water, and acids on some familiar substances, simple quantitative experiments, and exercises in systematic analysis. The volume thus provides elementary students with an instructive course of work in practical chemistry.

Marvels of Ant Life. By W. F. Kirby, F.L.S., F.E.S. Pp. viii + 174. (London: S. W. Partridge and Co., 1898.)

ANTS and their habits form a subject of perennial interest to general readers, so Mr. Kirby's popular account of the more remarkable phases of ant life should be successful. The text is lightly written, for the benefit of general readers who are entirely unfamiliar with insect life in its scientific aspects; but there is also much in it to interest attentive students of natural history.

LETTERS TO THE EDITOR.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*]

The Spectrum of Krypton.

PROF. RUNGE, in your last issue, points out that the wave-length of the bright green line of krypton is 5570·4 (Rowland's scale), while that of the auroral line is about 5571. In the paper presented to the Royal Society by Dr. Travers and myself on June 3, the wave-length is given as 5567·7. The wave-length was re-measured by Mr. Baly on June 7, and its value was found to be 5570·0. That of the feebler green was 5561·8, and of D_4, the yellow line, 5870·0. These values, read by means of a grating, are very close to those given by Prof. Runge. We hope to publish photographic measurements of the other lines shortly.

WILLIAM RAMSAY.

University College, London, November 15.

Stereochemistry and Vitalism.

ALTHOUGH Prof. Japp has already replied to the criticisms which have appeared in NATURE on his address to the Chemical Section of the British Association, we should be glad, in view of the interest taken in the matter, and also because we have been investigating externally compensated and optically active compounds for some years past, if you could find space in which we may continue the discussion and bring forward a few facts in support of our views.

In the first place, we will briefly summarise the main points on which there seems to be general agreement, as follows:—Compounds, optically inactive by external compensation, can be prepared under symmetric conditions—such compounds, under suitable and symmetric conditions may separate from solution in enantiomorphously related crystals; under symmetric conditions crystals of the two enantiomorphs are deposited in equal numbers, and the crystalline deposit as a whole, as well as the mother liquor, if separated, are both optically inactive.

Now Prof. Japp contended that, in order to obtain an optically active deposit or mother liquor from such an externally compensated compound (without the aid of some pre-existing asymmetric influence), an intelligently selective or vital force must be called into action, and consequently that vitalism determined the existence of optically active compounds in nature; in his reply he modifies his original contention by introducing the word "constantly"; but this modification makes very little, if any, difference to the arguments which we adduce. His critics, on the other hand, have attempted to show, with what success we do not venture to express an opinion, that chance alone, or other causes apart from vitalism, may have brought about the present occurrence of enantiomorphous compounds in organised nature.

Having frequently had occasion to study the spontaneous crystallisation of externally compensated substances, we had in mind various observations, especially some made during recent work, which led us, from the first, to doubt the validity of Prof. Japp's views. Let us consider, in the first instance, the case of sodium chlorate, a substance which separates from solution in enantiomorphously related crystals. On allowing saturated solutions of this salt to crystallise spontaneously, we found that in only two experiments out of forty-six were equal numbers of dextro-and laevo-rotatory crystals deposited (*Trans. Chem. Soc.*, 1898, 606), the percentage of dextro-rotatory crystals in the 46 crops varying from 24·14 to 77·36; nevertheless, the weighted mean percentage of dextro-rotatory crystals obtained was 50·08 ± 0·11. It is obvious, therefore, that on crystallising this substance under symmetric conditions equal numbers of dextro-and laevo-rotatory crystals are finally obtained, and yet in a single deposit one or other form may be present in large excess.

On the publication of Prof. Japp's address, we hastened to obtain further experimental evidence bearing on this point. For this purpose a saturated solution of sodium chlorate was allowed to evaporate spontaneously, three unselected crystals of the salt of unknown rotation being introduced as nuclei; after a week's time each of the three crystals had grown to a large size, and was very well developed. One of these, weighing 47 grams, was removed from the solution and broken into small pieces which were seeded into saturated solutions of the chlorate; the latter were then placed aside to crystallise. After a week's time these solutions were full of well-developed crystals, which were removed and examined; the crystals were 269 in number, and were all dextro-rotatory.

This experiment shows that an enantiomorphous system may originate from a non-enantiomorphous one without the introduction of any intelligently directive or enantiomorphous influence, and under conditions which might well arise in an inorganic non-enantiomorphous universe. This being so, it is illogical to assume in the present rudimentary state of our knowledge of the subject that enantiomorphism of this kind could not cause enantiomorphism in a system containing a substance such as racemic acid or some other externally compensated compound

Now, although a solution of sodium chlorate deposits on the average equal numbers of dextro-and laevo-rotatory crystals, this does not preclude the possibility of other similar compounds which separate from solution in enantiomorphously related crystals giving a preponderance of one or other form, owing possibly to enantiomorphous influences exerted by surrounding conditions, such, for example, as the earth's enantiomorphism; in fact, as we have already pointed out (*Trans. Chem. Soc.*, 1898, 611), observations in support of this view are not lacking, although they require, and are now receiving, further examination.

We have also shown (*Proc. Chem. Soc.*, 1898, 113) that, apparently, a close analogy exists between the behaviour of sodium chlorate and of an externally compensated mixture of dextro- and laevo-rotatory sodium ammonium tartrates; this parallel we are at present investigating. The first step in our examination of sodium chlorate was to ascertain the ratio between the numbers of dextro- and laevo-rotatory crystals deposited from solution, with the results briefly summarised above; obviously a similar step is necessary in the case of the mixed tartrates. The results which have been obtained in these experiments contrast remarkably with those recorded in the case of sodium chlorate, and are absolutely at variance with the views expressed by Prof. Japp. Ten such solutions have so far been examined, and in every case a strongly dextro-rotatory deposit was obtained, the mother liquor, of course, being strongly laevo-rotatory. We put these experimental results forward with considerable reservation as the work is not complete and we may discover some disturbing influence; but, inasmuch as attention has of late been concentrated on this fascinating subject by Prof. Japp's equally fascinating presentment of it, we feel compelled to make this short statement of the results up to the present obtained in developing the work which we have in hand.

Much more might be written with a view to suggesting the possible sequence of events which might have led to the present conditions of organised nature, but it is of little use attempting such a task until a great deal more experimental evidence is before us.

F. STANLEY KIPPING.
WILLIAM J. POPE.

THE following seems to me a perfectly possible, although purely hypothetical, way in which any amount of an optically active compound could be formed by chance chemical processes.

Let an admixture of chemical compounds be such that only one molecule of an optically active compound is formed. Or, if you like, let a volcanic explosion scatter a collection of equal quantities of dextro and laevo molecules in such a way that one molecule only falls in a certain pool of water containing inactive bodies in solution.

This single molecule must be either dextro or laevo. Let us suppose it is a dextro molecule.

Furthermore, let it be of such a nature that it can react catalytically with surrounding molecules in such a way as to produce in these an asymmetric atom:

e.g.

$$(1)\quad \begin{array}{l} \mathrm{C}d_2 \\ \| \\ \mathrm{C}ab \end{array} + \mathrm{RH}_2 = \begin{array}{l} \mathrm{C}d_2\mathrm{H} \\ | \\ \underline{\underline{\mathrm{C}}}ab\mathrm{RH} \end{array}.$$

$$(2)\quad \begin{array}{l} \mathrm{C}d_2\mathrm{H} \\ | \\ \underline{\underline{\mathrm{C}}}ab\mathrm{RH} \end{array} + \mathrm{H}_2 = \begin{array}{l} \mathrm{C}d_2\mathrm{H} \\ | \\ \underline{\underline{\mathrm{C}}}ab\mathrm{H} \end{array} + \mathrm{RH},$$

where *abcd* are any monovalent radical not containing an asymmetric carbon atom, while R is a dextro-rotatory bivalent radical. The first molecule formed, according to equation (1), will have the underlined C dextro or laevo, being determined by R being dextro.

When this decomposes according to equation (2) the $\underline{\underline{C}}$ will still be active, and one active molecule of $\begin{array}{l} \mathrm{C}d_2\mathrm{H} \\ \vert \\ \underline{\underline{\mathrm{C}}}ab\mathrm{H} \end{array}$ will have been produced.

But RH_2 is reproduced, and is consequently capable of repeating this action indefinitely, and of making an indefinite number of $\begin{array}{l} \mathrm{C}d_2\mathrm{H} \\ \vert \\ \underline{\underline{\mathrm{C}}}ab\mathrm{H} \end{array}$ molecules with activity of the same sign.

Furthermore, this action is scarcely to be distinguished in principle from the reactions brought about by unorganised ferments or enzymes.

W. M. Strong.

Helstonleigh, Champion Park, Denmark Hill, S.E., November 1.

It appears to me that Prof. Kipping and Mr. Pope unintentionally attribute to me opinions which I have never expressed, and which I do not hold. I never for a moment imagined that *in each separate crystallisation*—either of molecularly symmetric substances which, like sodium chlorate, may form either right-handed or left-handed crystals, or of the externally compensated mixture of dextro- and laevo-rotatory sodium ammonium tartrates, in which the asymmetry is molecular—equal amounts of the two kinds of crystals would necessarily be deposited. I never thought of this equality as holding good, except as the mean of a great number of experiments. In my address, when referring to Messrs. Kipping and Pope's results obtained with sodium chlorate, I therefore used the expression "on the average." Besides, I was acquainted with Landolt's experiments on the subject, which prove the same thing. In the case of the dextro- and laevo-rotatory sodium ammonium tartrates, the Pasteur-Gernez method of separating these by starting the crystallisation with a crystal of one of the two kinds, and Jungfleisch's experiments, to which I will refer more fully later on, were sufficient to make me aware of the influence of initial bias on crystallisation, and to prevent me from expecting equality, except as a mean result.

In fact, in these crystallisations everything depends on this initial bias; and in this respect, Landolt's experiments are especially instructive. His method (*Ber. d. deutsch. chem. Ges.*, 1896, p. 2410) consists in precipitating aqueous solutions of sodium chlorate by addition of alcohol. A magma of minute crystals is thus obtained, each of which must be either right-handed or left-handed. The crystals are then separated and ground to a fine powder; and this powder, suspended in a mixture of alcohol and carbon disulphide, is examined in the polarimeter. If both enantiomorphous forms are present in equal quantity, there will be no rotatory effect; whereas a preponderance of either form will be indicated by a rotation in the corresponding sense.

Landolt found that if the precipitation was rapidly effected by the sudden addition of alcohol, the powder was either inactive, or had a very feeble rotation. On the other hand, if the alcohol was gradually added, so as to produce slow precipitation, the powder displayed a marked rotation, which was in some cases right-handed, in others left-handed. The reason is obvious. In the former case, the crystallisation starts simultaneously from a vast number of independent centres; the chances are equal in favour of each centre being right-handed or left-handed; each centre will propagate its own kind; and thus the ratio of right-handed to left-handed forms will not differ very appreciably from unity. In the latter case, as Landolt points out, the crystallisation starts from only a few centres; in these, therefore, either the right-handed or the left-handed form may predominate, and, as sufficient time is given, the dominant form will influence the course of the crystallisation.

In Messrs. Kipping and Pope's slow crystallisations, every opportunity is afforded for any initial asymmetric bias to exercise its influence; and I should have been greatly surprised if the authors had obtained a result other than that which they describe.

There is, therefore, a marked difference between the formation of enantiomorphous crystals and of enantiomorphous molecules respectively, under symmetric conditions: namely, that the crystals propagate their own asymmetry, whilst the molecules, as I pointed out in my reply to Prof. Karl Pearson, do not—at least, so far as experiment informs us.

In the crystallisation of the externally compensated mixture of dextro- and laevo-rotatory sodium ammonium tartrates, one would expect a similar state of things to prevail, modified however by the circumstance that in this case, the two opposite asymmetries of the molecules themselves are pre-existent in the solution and must influence the result. One would expect variations, within limits, of the relative quantities of dextro- and laevo-salts deposited; but according to our present views, *the mean variations should occur equally in opposite directions.*

It is therefore with great surprise that I learn that in the ten experiments which Messrs. Kipping and Pope have hitherto made on this point they obtained in every case a strongly dextro-rotatory deposit. It is true that Jungfleisch (compare *Chem. News*, vol. 40, p. 231) published, in 1884, similar results. Jungfleisch's procedure was somewhat different from that of Messrs. Kipping and Pope. Instead of allowing the solution to crystallise spontaneously, he introduced simultaneously into the supersaturated solution, at opposite sides of the crystallising dish, a crystal of the dextro-rotatory and one of the laevo-rotatory salt. In all his experiments the former crystal increased in weight, and the mother liquor contained a corresponding excess of the laevo-salt. I confess that I have always attributed Jungfleisch's results to mere coincidence. It will doubtless be within Prof. Kipping's recollection that in April last I wrote to him calling his attention to these results, in connection with his joint work with Mr. Pope. Prof. Kipping replied (I quote from memory), that Jungfleisch's results were opposed to all that was known of the behaviour of enantiomorphs; that he (Prof. Kipping) did not regard them as conclusive; and that he proposed to repeat them. This he and Mr. Pope have now done; but from what I have just said, it is evident that the outcome of this repetition must have been as great a surprise to him as it is to me. I am glad to find, however, that the authors put forward their results with reserve, and that they contemplate the possibility of discovering some disturbing influence. If no such influence is at work, it is not merely the small matter of my particular application of the principles of molecular asymmetry that will have to go: it is these principles themselves. But I do not anticipate any such catastrophe. The vast accumulation of verified prediction of which the science of stereochemistry can boast, does not point to premises so unsound.

I will wait, therefore, for further light on Messrs. Kipping and Pope's later experiments before drawing any conclusion from them. As regards the experiments with sodium chlorate, I am at a loss to understand in what way they militate against my views. I no more expect equal numbers of right and left crystals to separate in any given crystallisation of sodium chlorate than I expect an unvarying alternation of heads and tails in tossing a coin. Nor do I perceive the application of the experiment in which they obtained none but right-handed crystals of the chlorate; inasmuch as, if they go on repeating it, they will obtain, just as often, none but left-handed crystals. The process will not *constantly* yield the same form.

I must also repeat that I do not regard the spontaneous formation of "optically active mother liquors," or other partial separations of enantiomorphs, especially when the separation may occur in either direction, as a solution of the problem. The separation of enantiomorphs in the living world is, in the overwhelming majority of cases, as I have pointed out in a previous reply, not partial but *total;* and it occurs *constantly* in one direction—only one form survives. This is another case where the word "constantly" applies—a word quoted by the authors, but otherwise ignored by them, except where they are discussing experiments which they themselves regard as requiring confirmation.

I think, moreover, that my critics might in justice take into account the disadvantage under which I laboured in having to compress into the limits of a brief address an account of a subject so vast and intricate. Many of my statements of important points were necessarily somewhat summary and inadequate: and most of the misunderstandings into which my various critics have fallen are, I am aware, due to this circumstance.

The University, Aberdeen, November 10.

F. R. Japp.

MR. STRONG'S suggestion is very ingenious, and I must admit that, *granting his premises*, the chance production of an unlimited quantity of a single asymmetric compound is conceivable. I had not thought of the possibility of one asymmetric molecule acting as a catalytic agent in the way he suggests. It would, however, have been perhaps simpler and more in accordance with the behaviour of enzymes, with which class of ferments he compares this supposed catalytic agent, if he had represented the second stage of the process as a hydrolysis; in which case, of course, the asymmetric group of the resulting compound would have contained hydroxyl in place of hydrogen.

Mr. Strong admits that the process is "purely hypothetical." I think I should go further than this, and say that, considered as an actual process occurring under chance conditions, it is grotesquely improbable.

The "volcanic explosion" carrying "one molecule" of an asymmetric compound into "a certain pool of water," seems to be a reproduction (on a reduced scale) of Prof. Errera's "vortex" which whirls "one simply asymmetric particle" into a particular "planet" (see NATURE, vol. lviii. p. 616, col. 2). Mental Calculations of a High Order.

THERE are probably among your readers some who are interested, by curiosity or for scientific purposes, in freaks of memory. I am not sure that what my memory has done is remarkable, although it is quite novel to me.

For many years I have been in the habit of using some useless exercise in mental gymnastics to divert my mind from the occupations of the day, and so get quickly asleep. Sometimes it would be extracting the letters of the alphabet successively from some passage in prose or poetry, keeping the number of each letter in mind, and finally counting all the letters in the passage, to make sure that I had allowed no letter to pass by me unnoticed. Again, I would try to think of all the famous poets, or generals, or sovereigns, or statesmen of all time, whom I could recall, in alphabetical order. Whatever might be the task I undertook I resumed it night after night, beginning as nearly as possible where I left off, and continue until I had completed it.

About a year ago the fancy took me to see how far I could go in raising, by mental process only, the number 3 to its high powers. At the beginning I would not have believed it possible to remember fifteen figures in their order. To my surprise I succeeded in raising 3 to the 44th power, making, if I remember rightly, a number of 22 figures. I did it by successive multiplications by 3, and without shortening the process in any way. I did not put a figure on paper until I had reached the 24th power; but always proved every result as far as I could by the nine test—a safeguard against substantially every error save those that might arise from transposition of figures. At the point mentioned I set the product down, and performed on paper this short process:

$$3^2 = 9;\ 3^4 = 81;\ 3^8 = 6561;\ 3^{24} = 6561 \times 6561 \times 6561.$$

As my mental result was wrong in four or five figures in the middle, so to speak, I knew that I must have transposed two figures somewhere between power 15 and power 20, so I went back and began over again. At the 24th power I was right, and so I was when I reached the 44th power.

That seemed to be as far as it was worth while to go, and I then began a more difficult exercise: to ascertain, as in permutations, the product of the numbers from one upward as far as I could go. I have carried the process up to, and including the number 37. The product is a number of 44 figures, whereof the last eight are 0's, which do not add to the effort of memory to retain them. To remember 36 digits in their correct order may not be a wonderful feat; it is so easy to me that I do not suppose it is unusual. But I can now remember, and have to-day written down and then repeated to my stenographer, successively, the product of the numbers to 35, to 36, and to 37, having respectively 33, 34 and 36 figures, beside the eight 0's with which each number ends, or 103 figures in all. How much further I could carry the process I do not know; I do not purpose attempting to ascertain.

I will add some facts that may be interesting.

(1) I verify my result after each multiplication: first, by proving that the sum of all the digits is a multiple of 9; secondly, by dividing it by 7, 11 and 13, not attempting to remember the quotient, but only the successive remainders, to be sure that the number divides evenly.

(2) Almost every product has some peculiar combination of numbers. For example, in the 35 result there are four 6's together; in the 36 the figures 6789 occur; the first six figures of the 37 product are 137,637; and so on.

(3) The work is done in groups of three figures, and almost every new factor in the multiplication gives some short process of multiplying. Before I begun with 37 it seemed impossible to multiply 34 figures by such a number, odd, large, and a prime number. But the fact that $37 \times 3 = 111$ soon suggested the way to make the process easy. The last nine figures (omitting 0's) of the 36 product are 481,508,352. Now $352 = 360 (3 \times 12 \times 10) - 8$. Then we have $111 \times 12 = 1332 \times 10 = 13,320$. $37 \times 8 = 296$. $13,320 - 296 = 13,024$. The multiplication of the next group is easy. $37 \times 500 = 18500$; add 296 $(37 \times 8) + 13$ ("carried") $= 18,809$. The next group, 481, is taken as $= 500 - 20 + 1$, and the number with the 18 "carried" from the last multiplication becomes 17,815,809,024.

(4) Does this exercise put me to sleep? O, yes, very quickly!

Boston, U.S.A., October 24. E. S.

The Leonids in 1868.

I WITNESSED the magnificent shower of Leonid meteors on the night of November 13–14, 1866. But I do not recollect seeing any published account of such a display in England in 1868. It occurs to me that the following observations may be worth publishing.

On November 5 in that year I was in Venice. Returning through Milan, I crossed the Alps in a sledge by the St. Gothard in a terrible snow-storm on the 7th, and reached Calais at midnight on the 13th. Neither sun, moon, nor stars had been visible since I left Venice. The Calais boat started for Dover about 1h. 30m. on the morning of the 14th. As we were leaving the port the clouds suddenly cleared off, and a splendid display of Leonids was visible. I judged the shower to be in every respect equal to that of 1866. Some of them were as bright as Jupiter, and left long trails in the sky which took two or three minutes to dissolve. The display kept up until we were within a couple of miles of Dover, when the clouds suddenly came on again and the sky was completely obscured.

Coventry, November 12. WM. ANDREWS.

The Smell of Earth.

"SEE, the smell of my son is as the smell of a field which the Lord hath blessed." Thus poetically spoke the Patriarch Isaac. The man of modern science tells us, prosaically, that the odour of moist earth is due to a bacterium, named *Cladothrix odorifera*. I write to ask if any one has yet accounted for the well-known and peculiar odour, yielded by clay and clayey rocks when breathed upon. This odour can scarcely be due to bacteria, for it is manifested by cabinet specimens more than twenty years old. Pure alumina appears to be odourless.

Leeds, November 12. C. T. WHITMELL.

Breath-Figure of Spider's Web.

A FEW mornings ago I noticed in my bath-room a spider's web spun right across one pane of the window, but not in actual contact with the glass, there being room for a house-fly to buzz up and down the pane without touching the meshes. My morning ablutions giving rise to some considerable quantity of vapour, I observed a very distinct breath-figure of the spider's web upon the glass. I accordingly removed the web and the spider. Next morning, in the absence of the web, on the renewal of the vapour conditions the breath-figure reappeared. I then wiped one half of the window dry with a towel. Now, after five mornings, the breath-figure is quite distinct upon the half which was not touched, and can be faintly seen on the wiped portion. OSWALD H. LATTER.

Charterhouse, Godalming, November 13.

A Second Crop of Apples.

I THINK perhaps it may be worth noting that apple-blossom was gathered in the neighbourhood of Exeter last week. Still more remarkable is the fact that a second crop of apples has made fair progress, as some at the farm of Gràs Lawn, close to the city, some "Red Quaranders" have been gathered, nearly the size of walnuts. Two of these, now somewhat shrivelled, are enclosed. JAMES DALLAS.

Exeter, October 14.

CONTINUITY OF WAVE THEORIES.[1]

CONSIDER the following three analogous cases:—I. mechanical, II. electrical, III. electromagnetic.

I. Imagine an ideally rigid globe of solid platinum of 12 centim. diameter, hung inside an ideal rigid massless spherical shell of 13 centim. internal diameter, and of any convenient thickness. Let this shell be hung in air or under water by a very long cord, or let it be embedded in a great block of glass, or rock, or other elastic solid, electrically conductive or non-conductive, transparent or non-transparent for light.

I. (1) By proper application of force between the shell and the nucleus cause the shell and nucleus to vibrate in opposite directions with simple harmonic motion through a relative total range of 10^{-3} of a centimetre. We shall first suppose the shell to be in air. In this case, because of the small density of air compared with that of platinum, the relative total range will be practically that of the shell, and the nucleus may be considered as almost absolutely fixed. If the period is $\frac{1}{32}$ of a second, frequency 32 according to Lord Rayleigh's designation, a humming sound will be heard, certainly not excessively loud, but probably amply audible to an ear within a metre or half a metre of the shell. Increase the frequency to 256, and a very loud sound of the well-known musical character (C_{256}) will be heard.[2]

Increase the frequency now to 32 times this, that is to 8192 periods per second, and an exceedingly loud note 5 octaves higher will be heard. It may be too loud a shriek to be tolerable; if so, diminish the range till the sound is not too loud. Increase the frequency now successively according to the ratios of the diatonic scale, and the well-known musical notes will be each clearly and perfectly perceived through the whole of this octave. To some or all ears the musical notes will still be clear up to the G (24756 periods per second) of the octave above, but we do not know from experience what kind of sound the ear would perceive for higher frequencies than 25000. We can scarcely believe that it would hear nothing, if the amplitude of the motion is suitable.

To produce such relative motions of shell and nucleus as we have been considering, whether the shell is embedded in air, or water, or glass, or rock, or metal, a certain amount of work, not extravagantly great, must be done to supply the energy for the waves (both condensational and rarefactional), which are caused to proceed outwards in all directions. Suppose now, for example, we find how much work per second is required to maintain vibration with a frequency of 1000 periods per second, through total relative motion of 10^{-3} of a centimetre. Keeping to the same rate of doing work, raise the frequency to 10^4, 10^5, 10^6, 10^9, 10^{12}, 500×10^{12}. We now hear nothing; and we see nothing from any point of view in the line of the vibration of the centre of the shell which I shall call the axial line. But from all points of view, not in this line, we see a luminous point of homogeneous polarised yellow light, as it were in the centre of the shell, with increasing brilliance as we pass from any point of the axial line to the equatorial plane, keeping at equal distances from the centre. The line of vibration is everywhere in the meridional plane, and perpendicular to the line drawn to the centre.

When the vibrating shell is surrounded by air, or water, or other fluid, and when the vibrations are of moderate frequency, or of anything less than a few hundred thousand periods per second, the waves proceeding outwards are condensational-rarefactional, with zero of alternate condensation and rarefaction at every point of the equatorial plane and maximum in the axial line. When the vibrating shell is embedded in an elastic solid extending to vast distances in all directions from it, two sets of waves, distortional and condensational-rarefactional, according respectively to the two descriptions which have been before us, proceed outwards with different velocities, that of the former essentially less than that of the latter in all known elastic solids.[1] Each of these propagational velocities is certainly independent of the frequency up to 10^4, 10^5, or 10^6, and probably up to any frequency not so high but that the wave-length is a large multiple of the distance from molecule to molecule of the solid. When we rise to frequencies of 4×10^{12}, 400×10^{12}, 800×10^{12}, and 3000×10^{12}, corresponding to the already known range of long-period invisible radiant heat, of visible light, and of ultra-violet light, what becomes of the condensational-rarefactional waves which we have been considering? How and about what range do we pass from the propagational velocities of 3 kilometres per second for distortional waves in glass, or 5 kilometres per second for the condensational waves in glass, to the 200,000 kilometres per second for light in glass, and, perhaps, no condensational wave? Of one thing we may be quite sure; the transition is continuous. Is it probable (if aether is absolutely incompressible, it is certainly possible) that the condensational-rarefactional wave becomes less and less with frequencies of from 10^6 to 4×10^{12}, and that there is absolutely none of it for periodic disturbances of frequencies of from 4×10^{12} to 3000×10^{12}? There is nothing unnatural or fruitlessly ideal in our ideal shell, and in giving it so high a frequency as the 500×10^{12} of yellow light. It is absolutely certain that there is a definite dynamical theory for waves of light, to be enriched, not abolished, by electromagnetic theory; and it is interesting to find one certain line of transition from our distortional waves in glass, or metal, or rock, to our still better known waves of light.

I. (2) Here is another still simpler transition from the distortional waves in an elastic solid to waves of light. Still think of our massless rigid spherical shell, 13 centim. internal diameter, with our solid globe of platinum, 12 centim. diameter, hung in its interior. Instead of as formerly applying simple forces to produce to-and-fro rectilinear vibrations of shell and nucleus, apply now a proper mutual forcive between shell and nucleus to give them oscillatory rotations in contrary directions. If the shell is hung in air or water, we should have a propagation outwards of disturbance due to viscosity, very interesting in itself; but we should have no motion that we know of appropriate to our present subject until we rise to frequencies of 10^9, 10×10^{12}, 400×12^{12}, 800×10^{12}, or 3000×10^{12}, when we should have radiant heat, or visible light, or ultra-violet light proceeding from the outer surface of the shell, as it were from a point-source of light at the centre, with a character of polarisation which we shall thoroughly consider a little later. But now let our massless shell be embedded far in the interior of a vast mass of glass, or metal, or rock, or of any homogeneous elastic solid, firmly attached to it all round, so that neither splitting away nor tangential slip shall be possible. Purely distortional waves will spread out in all directions except the axial. Suppose, to fix our ideas, we begin with vibrations of one-second period, and let the elastic solid be either glass or iron. At distances of hundreds of kilometres (that is to say, distances great in comparison with the wave-length and

[1] "Continuity in undulatory theory of condensational-rarefactional waves in gases, liquids, and solids, of distortional waves in solids, of electric waves in all substances capable of transmitting them, and of radiant heat, visible light, ultra-violet light." Communicated by Lord Kelvin, G.C.V.O., being the substance of a communication to Section A of the British Association at its recent meeting in Bristol.

[2] Lord Rayleigh has found that with frequency 256, periodic condensation and rarefaction of the marvellously small amount 6×10^{-9} of an atmosphere, or "addition and subtraction of densities far less than those to be found in our highest vacua," gives a perfectly audible sound. The amplitude of the aerial vibration, on each side of zero, corresponding to this is $1{\cdot}27 \times 10^{-7}$ of a centimetre.—"Sound," vol. ii. p. 439 (second edition).

[1] "Math. and Phys. Papers," vol. iii., art. civ p. 522.

great in comparison with the radius of the shell), the wave-length will be approximately 3 kilometres.[1] Increase the frequency now to 1000 periods per second: at distances of hundreds of metres the wave-length will be about 3 metres. Increase now the frequency to 10^6 periods per second; the wave-length will be 3 millim., and this not only at distances of several times the radius of the shell, but throughout the elastic medium from close to the outer surface of the shell; because the wave-length now is a small fraction of the radius of the shell. Increase the frequency further to 1000×10^6 periods per second; the wave-length will be 3×10^{-3} of a millim., or 3 mikroms,[2] if, as in all probability is the case, the distance between the centres of contiguous molecules in glass and in iron is less than a five-hundredth of a mikrom. But it is probable that the distance between centres of contiguous molecules in glass and in iron is greater than 10^{-5} of a mikrom, and therefore it is probable that neither of these solids can transmit waves of distortional motion of their own ponderable matter, of so short a wave-length as 10^{-5} of a mikrom. Hence it is probable that if we increase the frequency of the rotational vibrations of our shell to one hundred thousand times 1000×10^6, that is to say, to 100×10^{12}, no distortional wave of motion of the ponderable matter can be transmitted outwards; but it seems quite certain that distortional waves of radiant heat in aether will be produced close to the boundary of the vibrating shell, although it is also probable that if the surrounding solid is either glass or iron, these waves will not be transmitted far outwards, but will be absorbed, that is to say, converted into non-undulatory thermal motions, within a few mikroms of their origin.

Lastly, suppose the elastic solid around our oscillating shell to be a concentric spherical shell of homogeneous glass of a few centimetres, or a few metres, thickness and of refractive index 1·5 for D light. Let the frequency of the oscillations be increased to $5·092 \times 10^{14}$ periods per second, or its period reduced to ·589212 of a michron: homogeneous yellow light of period equal to the mean of the periods of the two sodium lines will be propagated outwards through the glass with wave-length of about $\frac{2}{3} \times$ ·589212 of a mikrom, and out from the glass into air with wave-length of ·589212 of a mikrom. The light will be of maximum intensity in the equatorial plane and zero in either direction along the axis, and its plane of polarisation will be everywhere the meridional plane. It is interesting to remark that the axis of rotation of the aether for this case coincides everywhere with the line of vibration of the aether in the case first considered; that is to say, in the case in which the shell vibrated to and fro in a straight line, instead of, as in the second case, rotating through an infinitesimal angle round the same line.

A full mathematical investigation of the motion of the elastic medium at all distances from the originating shell, for each of the cases of I. (1) and I. (2), will be found in a volume containing my Baltimore Lectures on "Molecular Dynamics and the Wave-Theory of Light," soon, I hope, to be published.

II. An electrical analogy for I. (1) is presented by substituting for our massless shell an ideally rigid, infinitely massive shell of glass or other non-conductor of electricity, and for our massive platinum nucleus a massless non-conducting globe electrified with a given quantity of electricity. For simplicity we shall suppose our apparatus to be surrounded by air or aether. Vibrations to and fro in a straight line are to be maintained by force between shell and nucleus as in I. (1). Or, consider simply a fixed solid non-conducting globe coated with two circular caps of metal, leaving an equatorial non-conducting zone between them, and let thin wires from a distant alternate-current dynamo, or electrostatic inductor, give periodically varying opposite electrifications to the two caps. For moderate frequencies we have a periodic variation of electrostatic force in the air or aether surrounding the apparatus, which we can readily follow in imagination, and can measure by proper electrostatic measuring apparatus. Its phase, with moderate frequencies, is very exactly the same as that of the electric vibrator. Now suppose the frequency of the vibrator to be raised to several hundred million million periods per second. We shall have polarised light proceeding as if from an ideal point-source at the centre of the vibrator and answering fully to the description of I. (1). Does the phase of variation of the electrostatic force in the axial line outside the apparatus remain exactly the same as that of the vibrator? An affirmative answer to this question would mean that the velocity of propagation of electrostatic force is infinite. A negative answer would mean that there is a finite velocity of propagation for electrostatic force. This velocity, according to views regarding conceivable qualities of aether described in my article "On the Reflection and Refraction of Light" (*Phil. Mag.*, vol. xxvi. 1888) might be greater than, equal to, or less than the velocity of light.

III. The shell and interior electrified non-conducting massless globe being the same as in II., let now a forcive be applied between shell and nucleus to produce rotational oscillations as in I. (2). When the frequency of the oscillations is moderate, there will be no alteration of the electrostatic force and no perceptible magnetic force in the air or aether around our apparatus. Let now the frequency be raised to several hundred million million periods per second; we shall have visible polarised light proceeding as if from an ideal point-source at the centre and answering fully to the description of the light of I. (2) The same result would be obtained by taking simply a fixed solid non-conducting globe and laying on wire on its surface approximately along the circumferences of equidistant circles of latitude, and, by the use of a distant source (as in II.) sending an alternate current through this wire. In this case, while there is no manifestation of electrostatic force, there is strong alternating magnetic force, which in the space outside the globe is as if from an ideal infinitesimal magnet with alternating magnetisation, placed at the centre of the globe and with its magnetic axis in our axial line.

[1] "Math. and Phys. Papers," vol. iii. art. civ. p. 522.

[2] For a small unit of length Langley, fourteen years ago, used with great advantage and convenience the word "mikron" to denote the millionth of a metre. The letter *n* has no place in the metrical system, and I venture to suggest a change of spelling to "mikrom" for the millionth of a metre, after the analogy of the English usage for millionths (mikrohm, mikro-ampere, mikrovolt). For a conveniently small corresponding unit of time I further venture to suggest "michron" to denote the period of vibration of light whose wave-length in aether is 1 mikrom. Thus, the velocity of light in aether being 3×10^8 metres per second, the michron is $\frac{1}{3} \times 10^{-14}$ of a second, and the velocity of light is 1 mikrom of space per michron of time. Thus the frequency of the highest ultra-violet light investigated by Schumann (·1 of a mikrom wave-length, *Sitzungsber. d. k. Gesellsch. d. Wissensch. zu Wien*, cii. pp. 415 and 625, 1893) is 10 periods per michron of time. The period of sodium light (mean of lines D) is ·589212 of a michron; the periods of the "Reststrahlen" of rocksalt and sylvin found by Rubens and Aschkinass (*Wied. Ann.*, lxv. (1898, p. 241) are 51·2 and 61·1 michrons respectively.

No practical inconvenience can ever arise from any possible confusion, or momentary forgetfulness, in respect to the similarity of sound between michrons of time and mikroms of space.—K.

THE SERUM TREATMENT OF RINDERPEST.

THE Report of the Colonial Veterinary Surgeon and the Assistant Veterinary Surgeons of the Cape of Good Hope is at the present time a document of very considerable interest, as it is possible from the facts there set forth to form some definite opinion as to the efficacy of the various methods of protection and treatment against rinderpest that have been recommended in the Colony. It appears that there is now a possibility of completely eradicating rinderpest from South Africa, not,

however, by means of the bile method—which was originally introduced by Koch, and appears to induce only a temporary though "active" immunity against the disease—but by means of the use of a "serum."

Drs. Turner and Kollé have, as already reported in these columns, found that it is possible to treat rinderpest successfully with a serum taken from animals which have already suffered from the disease produced either artificially or naturally and reinforced artificially. As a result of their investigations they are now in a position, with the aid of this serum, to control the course of the disease when artificially produced. As animals which have suffered from the disease are immune for a very considerable period, and as an animal that passes through an attack controlled by the serum is protected or "salted," as it is termed, this method has been adopted very extensively for the purpose of protecting animals in affected and suspected districts, and it is probable that in time it will oust the bile method completely; especially as it seems to be attended by fewer disadvantages than accompany the latter method, and can be carried out at less cost and with less loss of life amongst the cattle.

In working with the serum method in rinderpest it is necessary to know as much about the serum used as it is in the case of the treatment of diphtheria with anti-diphtheric serum; but one would imagine that at the Cape, where such enormous financial interests are concerned, there should be no difficulty in obtaining pure serum, the value of which has been carefully estimated, for the treatment of cattle suffering from the earlier symptoms of rinderpest. The relative cost would be slight even were it necessary to have a series of stations from which serum might be obtained, and taking into consideration the fact that this serum might have to be thrown away periodically; and one can scarcely imagine that a method which is described as being nearly perfect, should be allowed to remain unused because there is some slight difficulty as regards the supply of money and laboratory accommodation. In connection with this part of the question, it may be mentioned that it has been proved by experiment that the serum remains quite active for at least seven months. How much longer, still remains to be proved.

It will be remembered that on a former occasion it was pointed out that "it is useless to attempt to infect whole herds which have been previously inoculated with bile, because it does not seem possible to give all such inoculated animals the disease simultaneously. Most of the cattle will become sick after injection of virulent blood, but many may remain unaffected, as the immunity conferred by the bile is still effective and protects them, and they will in consequence not become salted. In these herds the most satisfactory course to pursue is for the owner to obtain a sufficient supply of serum, and inject the cattle as soon as they are observed to be sick, or the thermometer indicates a rise of temperature. Cattle already sick require a larger dose of serum than those that are healthy, and in severe cases a second may be necessary." This, however, as pointed out by the Veterinary Surgeon, is only an indication that the serum must be injected at a still earlier stage than has hitherto been done, so that it is necessary to apply the serum treatment to a herd of cattle which has previously been inoculated with bile soon after the injection of the virulent blood. Cattle that would have reacted to the blood take the disease in a modified form, and become salted; whilst those that would not react are no worse off for the addition of the serum, and probably have a slight addition to their passive immunity. The principal Veterinary Surgeon points out that "the fact that the immunity conferred by bile is now wearing off, makes it necessary for the farmers to take prompt action when the disease appears in their herds, and the fact that the bile immunity has ceased, gives greater prospects of success attending the application of the serum as above indicated." He also points out that infection is not nearly so frequently carried from artificially infected herds as from those which take the disease naturally.

Bearing on this question, there is an interesting article in the August number of the *Agricultural Journal and Mining Record*, published in Natal. The injection of bile, unless very carefully selected and preserved, appears in many cases to have set up chronic abscesses, from the description of which one would have said that they were actinomycotic or discomycotic in character, though this is a question which appears to deserve further investigation. From the annual report of the Commissioner of Agriculture for the year 1897, which appears in the same journal, it is evident that the farmers are now thoroughly alive to the importance of using bile where serum cannot be obtained, but of having recourse to serum inoculation along with the injection of blood from diseased animals, when this method can be properly carried out. The only real drawback, and this is a very slight one indeed, appears to be that in a few cases the injected blood appears to set up some form of "red water," whilst in a few instances a malarial parasite may be transmitted along with the blood.

An idea of the expenditure on rinderpest for the year 1897 may be gathered from the fact that the outlay for fences, &c., was nearly 170,000*l*. A very small proportion of this, added to the laboratory and veterinary outlay, would enable the department to cope with this disease in future, and to save the Colony an enormous sum, both directly and indirectly. Mr. Watkins Pitchford, in his report, states that where the departmental instructions for the use of the serum have been adhered to, good "and often brilliant results have repeatedly been achieved," and that he is right in his conjecture is very evident from the fact that when the serum is given in definite quantity on one side and rinderpest blood on the other, but simultaneously, a reaction is invariably set up in an unsalted animal; and even when this reaction is not very severe, the nature of the disease is so well defined and the results so successful that the animal is perfectly salted for some time against natural infection, and frequently against the injection of rinderpest blood: the severest test to which the method can be put. He believes thoroughly in the permanent immunisation of the herds as a means of stamping out rinderpest; but immunisation with bile, he believes, would fail, although it may be useful as a temporary measure where serum cannot be obtained. It must be remembered, however, that the immunisation of the first animal must as a rule be through the use of bile. He is strongly in favour of maintaining a trustworthy supply of serum for the cases as they may appear, and for the immunisation of any stock in herds which have already passed through the disease, but in which the immunity is still not quite sufficient. Those who are most intimately acquainted with the history of rinderpest, and of the recent work on serum-therapy in connection with this disease, are now satisfied that the extinction of rinderpest amongst Cape cattle is already practically accomplished.

NOTES.

ON Friday last, November 11, the Chemical Society gave a banquet in honour of six of its Past-Presidents who had been for over half a century Fellows of the Society. The occasion was the more noteworthy that these eminent chemists—Gilbert, Frankland, Odling, Abel, Williamson, and Gladstone—are in many cases ranked among those whose teaching has most deeply influenced chemical science. As M. Friedel said: "They form the finest phalanx of the fathers of chemistry

which exists in any country." The season of the year prevented many foreign chemists from attending, but a great number of letters and telegrams were received. Amongst the men of science present were Prof. Armstrong, Sir J. Wolfe Barry, Sir G. Birdwood, Sir J. Crichton Browne, Dr. Böttinger, Major-General Sir Owen Tudor Burne, Dr. T. Lauder Brunton, the Vice-Chancellor of Cambridge University, Sir Ernest Clarke, Sir W. Crookes, Major-General Sir J. Donnelly, Prof. Wyndham Dunstan, Dr. Dupré, Dr. Dyer, Mr. T. H. Elliott, Mr. H. M. Elder, Sir John Evans, Major-General Festing, Prof. Michael Foster, Prof. P. Frankland, Sir Archibald Geikie, Mr. W. Gowland, Mr. C. E. Groves, Mr. W. Hills, Sir W. Huggins, Prof. Judd, Dr. W. Kellner, Lord Lister, Major P. A. MacMahon, the President of Magdalen, Prof. Herbert McLeod, Prof. Raphael Meldola, Dr. Rudolph Messel, Prof. H. A. Miers, Prof. G. M. Minchin, Dr. Ludwig Mond, Mr. J. Fletcher Moulton, Q.C., M.P., Dr. Hugo Müller, Sir A. Noble, Prof. W. Ostwald, Dr. W. H. Perkin and Prof. W. H. Perkin, the Master of Peterhouse, Dr. Pye-Smith, Mr. Boverton Redwood, Prof. Ramsay, Lord Rayleigh, Lord Reay, Prof. Roberts-Austen, Prof. Rücker, Dr. Russell, Prof. Smithells, Prof. Sprengel, Sir G. Gabriel Stokes, Mr. J. W. Swan, Prof. J. M. Thomson. Dr. Thorpe, Prof. Tilden, Mr Tyrer, and Sir H. Trueman Wood. We hope to give in another issue a full report of the speeches made on the occasion of this highly successful gathering.

AT the opening meeting of the new session of the Royal Geographical Society on Monday, the President, Sir Clements Markham, referred to the exploration of the Antarctic regions as the most important geographical work of our time. He remarked that the Antarctic agitation had spread over Europe, and was no longer confined to Great Britain. The Germans would certainly despatch an Antarctic expedition in 1900. Dr. Neumayer, the great authority on terrestrial magnetism, had been working with this end in view for years. A steam-vessel, specially designed and equipped for Antarctic service, would be built at Bremerhaven. The German Government would help with funds and in other ways, and would lend officers, even although they might have to go some distance from the end of a telegraph wire. Dr. Erich von Drygalski, the distinguished Greenland explorer, would lead the scientific staff. Dr. Neumayer looked to us for co-operation. They would understand now why they could not wait for Admiralty changes of policy. It ought to be a Government expedition under naval discipline. But if our navy was to be deprived of her right, the next best thing must be done; they must appeal to the country. The Council of the Society had resolved to head the list of subscriptions, even if its name should stand alone. There were numerous calls upon their funds, but they had resolved to strain them to the uttermost for that great national work. The Council would head the list with the sum of 5000*l*.

PROF. MICHAEL FOSTER and Prof. Rücker, Secretaries of the Royal Society, were present at the opening meeting of the Royal Geographical Society, and expressed the sympathy of the Royal Society in the movement for Antarctic exploration referred to by the President. Prof. Foster remarked that the Government granted the sum of 4000*l*. a year for the cultivation of all branches of science, and it had been determined to make an application to the Committee which administered that 4000*l*. for a sum which should indicate how that Committee, representing not only the Royal Society, but all the scientific societies of this country, held in scientific esteem the proposed expedition. It was not so much the sum of money that would be obtained as a clear indication that that Antarctic expedition was an expedition of undoubted and great scientific value. He did trust, speaking on behalf of the Society, that the appeal which had been made by the President of the Royal Geographical Society might be responded to liberally. Prof. Rücker said he did not think too much stress could be laid on the fact that any connection with Germany was in this case of the very greatest importance; that observations which were taken simultaneously in different parts of the Antarctic regions would be worth far more than two sets of observations taken several years apart. It was a matter of the greatest importance that the two expeditions should go out at the same time and co-operate with one another in the sense that their observations should be carried out with a common object. Sir Joseph Hooker, Sir Erasmus Ommanney, and Sir Leopold McClintock also spoke in favour of the proposed expedition. Admiral Sir W. Wharton thought such an expedition would be best carried out under the auspices of the Admiralty, because it would be an expedition of great difficulty and would need strict discipline. But the Government had for the time being declined to afford their aid, and he was very much of opinion that a small expedition, which, he hoped, might be sent out by private aid, would be able to act as the pioneer of a larger expedition afterwards.

THE International Congress of Mathematicians will meet in Paris on August 6-12, 1900. The Mathematical Society of France has appointed committees of organisation, M. Poincaré being president of that concerned with scientific papers, and M. Darboux of that concerned with the other arrangements.

THE fiftieth anniversary of the death of Berzelius was celebrated at Stockholm, on October 7, by a memorial service, at which the King was present. In commemoration of this event a small volume, containing twenty letters exchanged between Berzelius and C. F. Schönbein in the years 1836-1847, edited by Prof. G. W. A. Kahlbaum, has been published by Benno Schwabe, Basel.

DR. CALMETTE, director of the Pasteur Institute at Lille, has been made an Officer of the Legion of Honour.

THE death is announced, at Rome, of Count Michele Stefano de Rossi, distinguished for his seismological work.

LETTERS recently received from Prof. A C. Haddon, who it will be remembered left England in March last with an exploring party, to continue his researches in the Torres Straits, report favourable progress of the work. The islanders are said to have been everywhere delighted with the phonograph; but misfortune early befell the party, in the miscarriage of a case containing their cinematograph films and Joly's colour-photography apparatus. We regret to add that Dr. Haddon has been the victim of two or three very mild attacks of fever, and that one of his companions has been more severely affected. The latest intelligence reports an improved state of health, and that they will be by now leaving for Bornea, with the exception of Dr. Rivers and Mr. Wilkin, who are expected to return to England before Christmas.

WE regret to see the announcement of the death, at the age of sixty-five, of the French electrical engineer, M. de Meritens, under distressing circumstances. The best-known invention made by M. de Meritens (remarks the *Engineer*) is his dynamo, and though one of the very first, if not the first dynamo of any practical value, it is still used at the present time, though only—to any extent, at least—for electric lighthouses. The dynamo is an alternating-current machine, and its field consists of permanent magnets. In efficiency it may fall short of machines of

ater type, but it has sterling merit, as is evidenced by the number of years it has been at work continuously, night after night, in the electrically-lit lighthouses of Great Britain, France, and other countries. The last in this country to be so fitted was that at St. Catherine's Point, in the Isle of Wight. This was in 1888. M. de Meritens' inventions did not by any means end here. In the early days of storage batteries he was to the front with an invention by which he sought to increase the surface of the plates immersed in the liquid by means of a plate of lead, so bent that pockets were formed in it, in which lead shot were placed. He also suggested many other forms of battery. M. de Meritens also invented a motor, and at one time turned his attention to electric welding, being the first to suggest using carbon for one pole and the metal to be welded for the other pole. He also attempted to improve on the original "candle" of Jablochkoff by utilising a third rod of carbon between the two outside rods, instead of the usual plaster of Paris or kaolin.

THE annual meeting of the Yorkshire Naturalists' Union has been postponed from Saturday, November 19, to December 17.

THE officers of the Botanical Society of America for the ensuing year are as follows:—President, Prof. L. M. Underwood; vice-president, Prof. B. L. Robinson; secretary, Prof. G. F. Atkinson.

DR. G. KLEBS has been appointed professor of botany and director of the Botanic Garden at Halle, and Dr. W. Schimper succeeds Klebs as professor of botany at the University of Basel. M. C. Sauvageau has been appointed professor of botany to the Faculty of Sciences at Dijon.

WE learn from the *American Naturalist* that the University of California has received from the Alaskan Commercial Company of San Francisco a large and valuable gift, consisting of the collections which the company has been accumulating for many years. The ethnological portion of the collection is especially rich, and is probably one of the best in existence. The collection also includes fossil remains of mammoth, and many skins and mounted specimens of mammals, birds, and invertebrates of the Alaskan region.

THE State of Hamburg has, according to the *Botanical Gazette*, just established, at Freihafen, a station for plant protection under the direction of Dr. C. Brick. The station will look after the introduction of injurious insects with the shipments of living plants from abroad, and its duties will include also the combating of plant diseases, the oversight of the schools of viticulture, and the inspection of vineyards and orchards in the Hamburg region, together with such questions as may arise in the prosecution of the work.

THE winter lecture season at the Imperial Institute opened on Monday with an illustrated lecture on "Trinidad, with some account of the recent hurricane in the West Indies," by Mr. Henry Caracciolo. The lectures are open to the public without payment, seats being reserved for Fellows of the Imperial Institute and their friends. The following are among the subjects of lectures before Christmas:—"The stalactite caves of New South Wales," by Mr. F. Lambert; "Gold-mining in Victoria," by Mr. E. Lidgey; "A national photographic record," by Sir J. Benjamin Stone, M.P.

A FEW particulars of Mr. Nikola Tesla's new method of electric power transmission are given in the current number of the *Electrical Review*. From the article it appears that the invention consists in transmitting electrical power without the employment of metallic line conductors, by taking advantage of the conductivity of the rarefied air existing in the upper regions of the earth's atmosphere. In order to make this practicable, special apparatus has been devised for the production and conversion of excessively high electrical pressure. Heretofore, it has been possible, by means of the apparatus at command, to produce only moderate electrical pressures, and even these, with considerable risks and difficulties. Mr. Tesla, however, claims that he has devised means whereby he is enabled to generate, with safety and ease, electrical pressures measured by hundreds of thousands, and even by millions of volts. He has also, during his investigations with such apparatus, discovered certain highly important and useful facts, which are said to render practicable his new system of transmitting electrical energy. Among these are the following: first, that with electrical pressures of the magnitude and character which he has been able to produce, the ordinary atmosphere becomes, in a measure, capable of serving as a true conductor for the transmission of the current; second, that the conductivity of the air increases so materially with the increase of electrical pressure and the degree of exhaustion, that it becomes possible to transmit, through even moderately rarefied strata of the atmosphere, electrical energy up to practically any amount and to any distance.

DR. C. LE NEVE FOSTER'S general report (Part iii.) and statistics relating to the output and value of the minerals raised in the United Kingdom, the amount and value of the metals produced, and the exports and imports of minerals, in 1897, has been published as a Blue Book. The following interesting facts are recorded in it. The output of coal last year was 202,129,931 tons, the highest hitherto recorded. The quantity of coal imported was no less than 37 million tons, and is likewise the highest on record. The output of iron ore reached 13¾ million tons last year. Aluminium and sodium appear in the report for the first time. It is pointed out that the production of alumina from alum clay or bauxite, and the extraction of the metal in the electric furnace, form a new branch of industry which was only started in the United Kingdom by the British Aluminium Company a short time ago. The alumina is prepared at works near Larne, County Antrim, and then despatched to Foyers in Inverness, where abundant water-power enables electricity to be generated cheaply. The Foyers installation is so far the largest water-power plant in the United Kingdom. The quantity of alumina extracted at the Larne works last year was 850 tons, value 15,300*l*., which produced 310 tons of aluminium, value 45,880*l*. With regard to sodium, the Aluminium Company, of Oldbury, near Birmingham, are practically the only makers of this metal in the United Kingdom. The quantity made last year was about 85 tons. At the present market price this output would be worth 12,750*l*. It is regretted that statistics concerning the quantities of magnesium and potassium are unobtainable.

THE total output of gold ore (auriferous quartz) in the United Kingdom in 1897 is given by Dr. Foster, in the report above referred to, as 4517 tons, the total value at the mines being 6282*l*. Turning to the ores of copper, lead, tin and zinc, Dr. Foster's tables do not present a satisfactory picture. Copper mining is a decaying industry. The output of lead ore is also declining: last year it was only 35,338 tons, being the smallest recorded during the last half-century. We only now produce one-half the amount of lead ore we did twenty-five years ago, and the same remark applies in the case of tin ore, while the values in both cases have decreased to one-fourth. The output of zinc ore, 19,278 tons, almost the same as it was in 1896, does not reach the average of the last quarter of a century. Of the so-called non-metallic minerals, clay, limestone, sandstone and slate are the most important, the value of the output in each case exceeding one million sterling. A new feature in the volume consists of

›unty summaries, showing by means of tables the output of ıch county. This will prove of great service to those who are ›ecially interested in the welfare of any particular county.

FROM Prof. Kr. Birkeland we have received a reprint of a ıper by him in the *Archives des Sciences physiques et ıturelles*, on the phenomena of attraction or "suction" of ıthodic rays by a magnetic pole. Since the author's previous ıper in 1896, the subject has been treated from a theoretical andpoint by Poincaré, whose views have been put to an ‹perimental test in a recently published paper by Wiedemann ıd Wehnelt. In the meantime Prof. Birkeland has made a ew series of experiments on the subject, and his present paper ɔt only affords a completion of Wiedemann and Wehnelt's ıvestigation, but furnishes a simple method for determining ıe relation existing between the velocity of the kathodic rays ıd the difference of potential (between anode and kathode) ıder which these rays are emitted.

MR. B. G. TEUBNER, of Leipzig, has commenced to bring ıt a new and important mathematical work in German, entled the "Encyclopaedia of the Mathematical Sciences." 'he object of the Encyclopaedia is to give in a concise form but ith the greatest possible completeness, and in a manner adapted ›r easy reference, all the newest results in both pure and pplied mathematics. It is also proposed to show by carefully-repared literary sketches, the historical development of mathe-hatical methods since the beginning of the century. The ıncyclopaedia will consist of six volumes, of about 3840 ages, of which the first will treat of Arithmetic and Algebra; ıe second, of Analysis; the third, of Geometry; the fourth nd fifth, of Applied Mathematics; and the sixth, volume of istorical and allied matter. In the detailed table of contents ıe absence of any reference (specific or indirect) to "Trigo-ometry" or "Circular Functions" is somewhat remarkable, eeing that even such a subsidiary subject as "Inversion" has a ʼhole section devoted to it under Geometry. The editors are Dr. H. Burkhardt (Zürich) and Dr. W. Franz Meyer (Königs-erg), and the work is being published under the auspices of he Imperial and Royal Academies of Munich and Vienna and he Royal Society of Göttingen. From the prospectus we learn hat "lengthy demonstrations will in general be omitted."

THE French Meteorological Office has recently issued its *Innales* for 1896, comprising three large quarto volumes. The rst volume, under the title of "Memoirs," contains a discussion y M. Fron of thunderstorms observed during the year, with harts showing their distribution for each day on which a storm ccurred. M. Moureau publishes the details of the magnetic bservations at Parc St. Maur, with a summary of the character-stics of the principal disturbances. These and the simultaneous ariations of earth currents are also shown by means of curves. 'here is an important work by M. Brillouin on contiguous rinds and clouds, in which the author studies the very compli-ated phenomena that may be produced in a region where two tmospheric strata mix together, and in which the amount of loud is unequal. M. Angot discusses the problem of the arometric measurement of heights, and has prepared new ables to facilitate the calculations. The attention of scientific ıen has been drawn to this question by the observations made uring recent international balloon ascents. A contribution to he rainfall of the region of the Upper Nile is made by M. de Iartonne. Monthly and yearly values are given for some forty tations, collected from various sources. There are also other apers of a minor character. Vol. ii. contains the results of bservations made at various stations. The colonial stations ave been considerably extended, especially in Africa, and some bservations are given for Timbuctoo, in the centre of that continent. Vol. iii. is devoted entirely to the discussion of rainfall observations; the number of stations included in the work exceeds two thousand.

IN connection with the journal *Photography*, silver and bronze medals are offered for the best sets of lantern slides relating to the subjects named in the following sections:—(1) The rivers of Great Britain; (2) the commercial ports of Great Britain; (3) the old churches of the United Kingdom; (4) British trees, plants, and flowers; (5) scenes among fishermen; (6) striking natural scenes in Great Britain (rocks, caves, trees, waterfalls, &c.). The competing slides should be in the hands of the editors by December 10. The object of the competition is to renew sets of similar slides which have for several years been circulated by *Photography*, without charge or fee, and have been largely used in schools for purposes of instruction.

TWO papers on the food of certain cuckoos and shrikes, based on investigations by Prof. F. E. L. Beal and Dr. S. D. Judd, are contained in *Bulletin* No. 9 of the Division of Biological Survey (U.S. Department of Agriculture). In the laboratory of the Biological Survey 109 stomachs of the yellow-billed cuckoo (*Coccyzus americanus*), and forty-six of the black-billed cuckoo (*C. erythrophthalmus*), taken between May and October, were examined. The results show that of the 155 stomachs of both species only one contained any vegetable food. It appears that the insect food of these birds consists of beetles, grasshoppers, cicadas, bugs, ants, wasps, flies, caterpillars, and spiders, of which grasshoppers and caterpillars constitute more than three-fourths. The great majority of the insects found in the stomachs were harmful kinds. It is a matter of common observation that cuckoos feed largely on caterpillars, and stomach investigations not only confirm this, but show that, unlike most other birds, they eat freely of hairy and bristly species. Nearly half of the food of the birds examined was found to be caterpillars. Considering the number of grasshoppers, locusts, and other insects that cuckoos eat, in addition to caterpillars, it is evident that from an economic point of view these birds are two most valuable species, and as they have not been convicted of doing any harm, they should be protected and encouraged in every possible way. Besides insects proper, Prof. Beal found a number of spiders in the stomachs he examined, most of them the long-legged kinds commonly known as "daddy longlegs" (*Phalangidae*). One stomach contained seven, the mass of tangled legs looking like a bunch of coarse hair. When we consider the disagreeable odour of these spiders, their long legs, and the fact that their bodies have the texture of sandpaper, we are again forcibly reminded that tastes differ. But the most remarkable thing which the birds examined had eaten was a small tree frog (*Hyla*). which had been swallowed whole!

DR. S. D. JUDD investigated the food of two species of shrikes, and the results are given in the *Bulletin* referred to in the foregoing note. One species, the loggerhead shrike (*Lanius ludovicianus et sub-spec.*) is a permanent resident of the United States; the other, the butcherbird (*Lanius borealis*), is a migrant from the north. From the investigation it appears that the food of the butcherbird and loggerhead, as shown by 155 stomachs collected during every month in the year, and in an area extending from California to the Atlantic coast, and from Saskatchewan to Florida, consists of invertebrates (mainly grasshoppers), birds, and mice. During the colder half of the year the butcherbird eats birds and mice to the extent of 60 per cent., and ekes out the rest of its food with insects. In the loggerhead's food, birds and mice amount to only 24 per cent. A table showing percentages of principal elements of food of the butcherbird and loggerhead indicates that the loggerhead's beneficial qualities

outweigh 4 to 1 its injurious ones. Instead of being persecuted the bird should, therefore, receive protection.

CORNWALL is to be congratulated upon the success of the efforts its Technical Instruction Committee are making for the benefit of fishermen, through Mr. J. T. Cunningham, the County lecturer on fishery subjects. The report of the executive committee for fisheries for the year 1897–98, is almost entirely devoted to a valuable statement by Mr. Cunningham on records of sea fishing and sea temperature, experiments on oyster culture and lobster rearing, fish and net curing, and other matters concerning the science and handicraft of sea fisheries. Among the interesting items referred to in his report, is the fact that at the beginning of every season male crabs are always more numerous in the pots than females. Their number increases gradually till May or June, when it gradually diminishes; while the number of females taken does not reach its maximum till June or July, and then they are twice as numerous as the males, and they usually continue to be more abundant than the males until the end of the season. On the other hand, practically the same number of male lobsters are caught as female. The observations of surface temperature, made in connection with these fisheries, are of great service in indicating the influence of temperature upon the number of fish taken in various months. With regard to lobster rearing, Mr. Cunningham reports that important and gratifying success has been obtained, and much precise knowledge has been gained concerning the particular details of treatment on which the life and death of the larvae depend. His observations have convinced him that the opinion that swimming lobster larvae in the sea capture and feed upon other swimming creatures, especially other small swimming crustaceans, is wrong. He holds that lobster larvae are, like the adults, carrion feeders, and are not in the habit of pursuing or capturing live food at all.

MESSRS. DUCKWORTH announce for publication "A Glossary of Botanical Terms," by Mr. B. Daydon Jackson; and a "Textbook of Agricultural Botany," by Mr. J. Percival.

MESSRS. J. M. DENT AND CO. announce that after the December number *Natural Science* will be published by Mr. Young J. Pentland, of Edinburgh, who has acquired all future rights.

MESSRS. W. WESLEY AND SON have just issued a new Catalogue (No. 132 of their Natural History and Scientific Book Circular), giving a descriptive and classified list of 1500 books and pamphlets on the natural history of Great Britain and Ireland. The arrangement of works under the names of the English counties, Wales, Scotland and Ireland, will be of service to collectors of local fauna and flora.

THE following new editions of works already reviewed in NATURE have been received:—The third edition of Prof. Grenville Cole's "Aids in Practical Geology" (London: Charles Griffin and Co.) The work has been completely revised and enlarged; many additions of practical service to the geologist have been made, and all important factors of geological progress since 1893, when the second edition appeared, have been taken into consideration.—Messrs. Slingo and Brookes's well-known volume on "Electrical Engineering for Electric Light Artisans and Students" has been published in a revised and enlarged edition by Messrs. Longmans, Green, and Co. The work now occupies 780 pages, and it provides students with sound information concerning direct and simple alternating currents, the machinery and apparatus connected therewith, and their most important applications.—The tenth edition of Mr. C. Haughton Gill's "Chemistry for Schools" (Edward Stanford) has been published. Dr. D. Hamilton Jackson is responsible for the revision of the book and the additions made to bring it into line with the new regulations in chemistry for the London University Matriculation Examination.—The second edition, revised and enlarged, of Dr. Lassar-Cohn's "Chemistry in Daily Life," translated by Mr. M. M. Pattison Muir, has been published by Messrs. H. Grevel and Co.

THE additions to the Zoological Society's Gardens during the past week include two Pumas (*Felis concolor*, ♂ ♀) from the Argentine Republic, presented by Mr. Ernest Gibson; a Hamster (*Cricetus frumentarius*), European, two Bennett's Wallabies (*Macropus bennetti*) from Tasmania, a Gentoo Penguin (*Pygosceles taeniatus*) from the Falkland Islands, a Gold Pheasant (*Thaumalea picta*, ♀) from China, two Elephantine Tortoises (*Testudo elephantina*) from the Aldabra Islands, deposited; two Japanese Deer (*Cervus sika*, ♂ ♂) from Japan, received in exchange; an Axis Deer (*Cervus axis*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE LEONIDS.—Unfortunately for observers in the neighbourhood of London, a fog more or less continuously hung over their heads on the nights of Sunday, Monday and Tuesday, and rendered observations of the expected meteor shower impossible. Observers at the Solar Physics Observatory, South Kensington, were only able to observe two or three meteors during these nights. One of special brilliance, on the night of Monday, at 10.48 G.M.T., shot across the sky from east to west, its paths extending at least 45 degrees. This was undoubtedly a fine Leonid; but its path could not be traced, as fog and cloud hid the stars from view.

Mr. R. H. Scott informs us that the meteorological reporter at Jersey (Mr Fisher, at St. Aubin's) has reported to the Meteorological Office that a meteor shower was observed there at 10 p.m. on Monday.

From a New York telegram, published in one of the daily papers, we gather that the shower was observed in America on the night of the 14th, but it did not attain the expected brilliancy. Prof. Young is said to describe the shower observed as faint, while at the Lick Observatory the meteors were said to be small and not marked by extraordinary brilliancy.

A GLOBE FOR METEOR OBSERVERS.—Every observer, who has plotted the trails of meteors on star charts, knows that errors of projection arise which are due to the difficulty of plotting accurately the whole length of the trail. If the points of beginning and end of the visible trail be mentally noted and marked off on a star chart, then the line joining these two points does not represent the actual trail of the meteor, in consequence of the fact that the path in the heavens is on a sphere, and that on the chart is on a plane. To avoid such discrepancies it is always better to use a celestial globe, when this difficulty is eliminated. The ordinary celestial globe is, however, not well adapted for recording meteor observations, as it must be illuminated from the outside by a lamp, as the observer is in the open air.

A globe arranged especially for use when such observations are being made, recently invented by M. Pietro Maffi, is described in the French journal *Cosmos*, and should be found very serviceable. It consists of a glass hollow sphere mounted on two vertical supports, and capable of adjustment as regards latitude. The outer surface is marked with the brighter stars of each constellation and the Milky Way, and there is also means of obtaining directly the right ascension and declination of any point on the globe. The inside contains two small electric lamps in connection with accumulators in the stand, so that the whole surface of the sphere with the constellations may be seen clearly. Directly a meteor is seen its path can be plotted, and when note is taken of its exact position a wet sponge is all that is necessary to erase it.

The globe and stand, as it appears in the illustration accompanying the article, seems rather elaborate: but there is apparently no reason why a more simple and cheaper form should not be made, for its use then would be more widely distributed.

EPHEMERIDES OF COMETS AND PLANETS.—Many readers of this column will be very glad to know that from the beginning of next year it will not be necessary to turn up back numbers of the *Astr. Nach.* to find the ephemerides of comets and planets for observational purposes. Prof. H. Kreutz tells us (*Astr. Nach.*, No. 3527) that he has been asked from several sides to supply this information separately; that is, in addition to that published in the numbers of that journal, and he has made the following arrangements. Those who are subscribers to that journal may, by paying an additional sum of ten marks yearly, obtain such information, provided that notice of such requirement is given directly, and applications are sufficient in number to indicate a decided want in this respect. We hope that many of our readers will think fit to take advantage of this very useful change.

We may mention that it would be a good opportunity for keeping to one system of publication, and that the Right Ascensions, for instance, might always be given in time, and not in degrees, as is often the case.

THE NEBULOUS REGION ROUND 37 CYGNI.—Although there may be countless nebulae in the heavens symmetrical in form, there are others which seem to have absolutely no sense of regularity. Such a nebulous region is that comprised between 20h. 51m. 24s. and 21h. 0m. 43s. in Right Ascension, and in Declination between $+42° 56'·5$ and $+44° 51'$ (epoch 1900). An excellent reproduction of the greater part of this region appears in *Knowledge* for November, and is taken from a fine negative obtained by Dr. Isaac Roberts in October 1896. A careful study of the photographic appearance of this large cosmical mass shows, as Dr. Roberts remarks, several indications of fission, as well as evidence of *loci* of vortical disturbance in different regions; but, for the main part, irregularity is the striking feature. In his description of this nebulous region, Dr. Roberts brings up the question of the connection between the stars apparently immersed in the nebulous mass and the nebula itself. In regular, such as spiral, nebulae, Dr. Roberts had previously come to the conclusion that many of the stars immersed are not stars, as we are generally acquainted with, but star-like condensations, the result of condensations in the nebula itself. In the irregular nebula in question, in which the whole surface area of this cloud of nebulosity is covered with stars, ranging from the ninth to the seventeenth magnitude, very few of the stars can be pronounced "as being actually involved in, and forming part of, the nebulosity." Dr. Roberts' evidence for assuming that those what he terms "apparently finished stars" are between us and the nebulosity is, in his own words, as follows:—"If the stars were beyond the nebulosity their photo-discs would on the negative appear less bright, and their margins be more or less nebulous; whereas only those stars which appear involved in the nebulosity present these appearances. Of course, it is a fair subject for argument that those nebulous stars which appear to be involved in the nebulosity are not so in reality, but seem thus because they are beyond it in our line of sight. But this argument is much weakened, if not entirely destroyed, when we find on examination of the negative that those faint, star-like condensations are not only nebulous themselves, but they follow the curvatures found in various parts of the nebulosity; thus we are driven to infer that the stars are the nearer bodies to us, and that the nebulosity lies beyond the stars."

WOLSINGHAM OBSERVATORY CIRCULAR, NO. 48.—Mr. T. E. Espin in this circular informs us that a star, magnitude 8·4, Type IV., not in B.D. was found on November 13 in Right Ascension 4h. 19m. 49s., Declination $+ 39° 32' (55)$. The star in the Andromeda Nebula was seen on November 10, closely following the nucleus. The one found in 1886 was preceding.

THE EXTRACTION OF NICKEL FROM ITS ORES BY THE MOND PROCESS.[1]

THE Mond process marked an entirely new departure in metallurgical practice and in the principles which had hitherto guided it. It depended on the remarkable property possessed by nickel of forming a volatile compound with carbon-monoxide, from which metallic nickel might be released if the gaseous compound was heated to 180° C.

The methods hitherto employed for extracting the metal from its ores involved concentrating the nickel either as a sulphide (matte or regulus), or as arsenide (speise), followed by either dry or wet treatment; and the metal had to be refined, mainly with a view to separate it from associated carbon.

In 1889 Dr. Ludwig Mond, in collaboration with Dr. Carl Langer, had been engaged upon a method for eliminating the carbon-monoxide from gases containing hydrogen. They had been guided by the observation that finely-divided nickel removed carbon from carbon-monoxide at a temperature of 350° C., converting it into carbon-dioxide, whereas the dissociation of carbon-monoxide by heat alone, according to Victor Meyer and Carl Langer, remained incomplete at the high temperature of 1690° C. The experiments were carried out in conjunction with Dr. Friedrich Quincke; finely-divided nickel, formed by reducing nickel oxide at 350° C. by hydrogen, being treated with pure carbon-monoxide in a glass tube at varying temperatures. The gas escaping from the apparatus was ignited, and while the tube containing the nickel was cooling, the flame became luminous, and increased in luminosity as the temperature sank below 100° C. Metallic spots were deposited on a cold plate of porcelain held in this luminous flame, and on heating the tube through which the gas was escaping a metallic mirror was obtained, while the luminosity of the flame disappeared. These metallic deposits were found to be pure nickel. Nickel carbonyl was then isolated in a liquid state, and it was possible to produce it with facility in any desired quantity. It could be readily distilled without decomposition, but on being heated to 150° C., the vapour was completely dissociated, pure carbon-monoxide being obtained and the nickel being deposited in a dense metallic film upon the sides of the vessel.

No other metals which were submitted to investigation showed indications of combining directly with carbon-monoxide except iron. The discovery that in a mixture of metals only nickel and iron would form volatile compounds with carbon-monoxide, and that they could, therefore, be separated from the other metals, induced Dr. Mond to arrange experiments with ores containing nickel, cobalt, iron and copper, such as "kupfer-nickel" and "pyrrhotine." The experiments afforded such promising results that apparatus of considerable size, though still within the limits of the resources of a laboratory, was set up, and in it several pounds of ore could be treated with carbon-monoxide. The principal nickel ores which were metallurgically treated contained the nickel in combination with arsenic and sulphur, besides other metals and gangue. These ores had first to be submitted to calcination, in order that the nickel might be present in the form of oxide, and to drive off, as far as practicable, the arsenic, sulphur, and other volatile bodies. The resulting oxide of nickel was treated with reducing gases, such as water-gas or producer-gas, in order to convert the oxide of nickel into finely divided metallic nickel, and the material containing it was cooled to about 50° C., and was treated with carbon-monoxide.

In 1892 an experimental plant on a large scale had been erected at Smethwick, near Birminghan. The process began with "Bessemerised" matte; it ended with the market product, commercial nickel. The Bessemerised matte proceeded to the first operation of dead roasting, after which the matte contained 35 per cent. of nickel, 42 per cent. of copper, and about 2 per cent. of iron. It then passed to the second operation for the extraction of part of the copper (about two-fifths) by sulphuric acid, the copper being sold as crystallised sulphate of copper. The residue from this process contained about 51 per cent. of nickel, and it passed to the third operation for reducing the nickel. Incidentally, the remaining copper was reduced to the metallic state, care being taken to avoid reducing the iron. This was effected in a tower provided with shelves, over which mechanical rabbles passed, the reducing agent being the hydrogen contained in water-gas. The temperature did not exceed 300° C., and should be kept lower when much iron was present. From this tower the ore was conveyed continuously to the fourth operation of volatilisation, in which part of the nickel was taken off by carbon-monoxide and formed the compound nickel carbonyl. The formation of this volatile compound was effected in a tower similar to the reducing tower, but the temperature was much lower, and did not exceed 100° C. From the volatiliser, the ore was returned

[1] Abstract of paper read at the Institution of Civil Engineers, on November 8, by Prof. W. C. Roberts-Austen, C.B., F.R.S.

to the reducer, and it continued to circulate between the reducing and the volatilising stages for a period which varied between seven days and fifteen days, until about 60 per cent. of the amount of nickel had been removed as nickel carbonyl. The residue from this operation, amounting to about one-third of the original calcined matte, and not differing much from it in composition, was returned to the first operation and naturally followed the same course as before. The nickel carbonyl produced in the fourth operation passed to a decomposer, which consisted either of a tower or a horizontal retort heated to a temperature of 180° C., so as to decompose the nickel carbonyl and release the nickel in the metallic form, either on thin sheets of iron or, preferably, on granules of ordinary commercial nickel. Carbon-monoxide was in turn also released, and was returned to the volatiliser for taking up a fresh charge of nickel. When the operation was in progress, the gaseous carbon-monoxide and the partially reduced oxide of nickel and copper continuously revolved in two separate circuits, which joined and crossed each other in the volatiliser. The commercial product contained 99·8 per cent. of nickel.

The author proceeded to a description of the working as he saw it in full operation in Smethwick a few months ago. The plant had been working for some time, and about 80 tons of nickel had already been extracted from different kinds of matte. The results were quite satisfactory, and pointed to the conclusion that the process was well able to compete with any other process in use for the production of metallic nickel.

The process would always occupy a prominent position in chemical history, and there appeared to be no reason why it should not play an important part in metallurgical practice. Its application in Canada to the great nickeliferous district of Sudbury would probably contribute to the development of the resources of the great Dominion.

NATURAL HISTORY NOTES FROM YUNNAN.[1]

I LEFT Mengtze in the end of January with a caravan of mules, some forty, carrying stores, &c. I had three mule-loads, *e.g.*, of silver. The journey here took eighteen days, rather easy stages. The country passed through was very varied. I was in good spirits, rode nearly all the way, and enjoyed the trip very much. I crossed three large rivers *en route* by pontoon and suspension bridges ; the latter very well made, of iron rods joined by rings at the ends, the best specimens I have seen of Chinese blacksmith's work. At these river crossings we reached low levels, about 1800 feet above the sea, and came into tropical vegetation, which I never find at all interesting. At Yuenchiang, on the Red River, the ugly-looking shrub *Calotropis gigantea* was in flower, and there was a great display of the tree-cotton, *Bombax*, in flower, without any leaves, looking like an artificial candelabrum affair more than a living tree. These and some *Areca* palms were the only things of note. At the higher levels vegetation was at a dead point and I collected very little, one or two species of *Clematis*, two Rhododendrons : the very curious *Scolopendrium Delavayi*, which I had never seen before, I found one day on a shady bank where I stopped for tiffin. I also found, at the same place, two plants of *Abutilon sinense*, which had been sent by me from Ichang, and an *Antrophyum*, which may be new. I also came across *Lonicera Bournei* in flower ; it is of no value as an ornamental plant. There was very little forest until after Talang, when we passed one or two days through almost continuous pine forest, varied here and there by little woods of evergreen oaks. Here, rather to my surprise, I learned that the peacock exists in the wild state, and it is quite common in the forest south of Szemao. These pine forests had not a plant in flower amongst them. I noticed, however, two little woods made up of an *Abies*, new to me, but I only found one cone. However, I am not pretending now to give any account of the trip botanically, as it would require too much time to get my notes in order at the moment. On the eighteen days I may have collected about thirty plants in flower. At one or two places I might have done a lot of collecting if I could have stayed for a day or two, but I was travelling on official business, and could not tarry.

The main interest of the route was the aborigines, or non-Chinese races. Chinese here and there dwell on the little tracts of good land which are found in the high-lying valleys and plains of the plateau, and I passed through five or six largish towns mainly peopled by Chinese. But the larger part of the population was made up of aborigines. Whether the ethnology of this part of the world will ever be satisfactorily explained is doubtful. There seems to be the same variety in the human being as exists in the vegetable world in the same region, and there is a strange blending of races of Chinese, Malay, Negrito, perhaps even Caucasian here.

The greatly increased interest in China at home will, I hope, give a stimulus to the study of the history of the social evolution of the Chinese, which is calculated to bring out many important lessons for ourselves. There have been, as it were, two parallel developments of the human race, one on the west of Europe-Asia, the other on the east side, very little dependent on each other. At the start, the Chinese seem to have been fairly equal to the Westerners ; and even in the middle ages, judging from the way in which mediaeval travellers wrote, Chinese civilisation was quite as good as that of Europe. The decay of manly spirit, brought about by the idea that war is immoral, the low position of woman, the absence of an hereditary aristocracy holding up ideas of honour and probity and constantly acting as a check on philistinism, the government by officials selected by competitive examination in ancient classics and trivialities akin to Latin verse, all these causes must have been acting disastrously to have brought an intelligent race into such a low position.

There is a good deal of wooded country at no great distance from Szemao, and the mountains run up to nearly 6000 feet, but there is an absence of the sharp and precipitous kind of mountain and valley, and the flora in consequence is very uniform and not nearly so interesting as Mengtze nor so rich in species. Hills clad with pine and oak are almost barren in interesting plants, and I haven't come on any of those dark ravines and steep wooded cliffs which are the joy of the botanical collector. There is a great absence (perhaps the autumn will make a better show) so far of ferns and herbaceous plants. What one collects is mainly trees and shrubs and climbers. There is a fair number of epiphytic orchids. The common plants are not the common plants of Mengtze, in fact the two floras are very different. Szemao will possibly turn out very like the Shan country where Sir Henry Collett collected, and Indian forms not hitherto recorded from China are frequent enough. One curious thing occurs here as well as at Mengtze, *i.e.* the occurrence of two or three species of the same genus in precisely the same locality and often flowering at the same time.

The woods near Szemao are full of birds, and the notes are exquisite, and to be heard in perfection in these days of showery weather, for the rainy season has begun. When the sun gets out the cicadas start such a racket that one can hear nothing else. I have not told you of the jungle-fowl ; this is, I believe, *Gallus bankiva*, the original form of the farmyard fowl. They are very common in the forests and woods here, and are simply gorgeous. They are glorified bantams, the colours having a brilliancy that seems abated in the domesticated kind. They crow and cackle and behave in the woods just as a farmyard fowl would do, only they are a little shyer of man. Occasionally one sees a flying-squirrel, a big black one, sailing in the air from tree to tree, and I saw the other day what I thought was a calf ; it turned out to be a red-coloured deer, which speedily bolted with an upturned tail, white beneath like a rabbit's. It is very hard to believe that this particular deer, which only occurs, so far as I know, one or two together, never a herd, derives much advantage in life from this white-signal tail.

In many of the Mengtze and Szemao trees and shrubs the flowers occur on the branches below the leaves, and not on the peripheral surface of the tree, as in ordinary cases. Many lianas have this peculiarity. These are all forest plants, and I think the explanation is that in forests there are two surfaces open to insect-visitors, the top of the forest and the bottom. Some trees and shrubs and climbers cannot get to the top, so they have their flowers at the bottom. But of course this explanation is only a guess. There is no time for me to make any observations of the kind necessary ; if one could spend six months on end in a forest, one could observe, measure, &c. The *Mucuna sempervirens* of Ichang was a splendid example of this peculiarity. There was in one specimen a dense wall of foliage climbing over trees, interlaced with them, &c., nearly 200 feet by 100 feet, while the main trunk of the climber close to the ground was covered with

[1] Abridged from a letter to Mr. Thiselton-Dyer, from Dr. Augustus Henry, published in the Kew *Bulletin* for November (No. 143).

flowers which were easily visited by thousands of insects of all kinds.

There is quite a little group of shrubs which occur on the banks of rivers (and often in beds of streamlets) that overflow. These shrubs are submerged often and are not hurt. These *fluviatile* shrubs have a certain facies, very difficult to describe. There must be thirty or forty species of them in the Yunnan river valleys. These shrubs do not occur elsewhere than on banks or in the beds of streams. The last one I have found is a very fine species of *Ficus*. This class of shrub would be a nice enough problem for some one to work out.

I hope you will try and get a young Cambridge or Oxford botanist to come to this part of the world, do some naturalist work, and collect seeds and live plants for cultivation. China is a very easy country to travel in, and expenses of travelling are not heavy. The mountainous regions of Yunnan and Szechwan are very healthy besides.

TECHNICAL INSTITUTIONS IN ENGLAND.

THE current number of the *Record* of Technical and Secondary Education contains some encouraging statistics with regard to the establishment, extension, and adaptation of permanent technical schools and institutions in England since the passing of the Technical Instruction Act, 1889. The primary object of the inquiry (the results of which are now published) was to ascertain the amount of money sunk in buildings for technical education by local authorities, but some valuable information regarding certain details of organisation was obtained at the same time, and has been incorporated in the article. The statistics do not take into consideration either higher grade schools or schools governed by schemes under the Endowed Schools Acts and other secondary schools; but they refer to all the various types of permanent technical institutions, and, consequently, there are included domestic economy schools, agricultural and horticultural schools and colleges, farm schools, and dairy schools. It was intended to take in university colleges so far as they included technical or agricultural departments, but it is stated that as these institutions are largely non-local in character, supplying certain educational requirements in large areas by reason of the financial assistance of local authorities, they have been excluded. The following summary, given by the *Record*, shows the developments which have taken place, but, as has been mentioned, it only partly represents the progress made since 1889, as it does not take into consideration secondary schools serving the purpose of technical institutes.

The figures which appear under the head of "counties" refer to those institutions which have been directly established, and are being exclusively maintained, by County Councils.

(1) NUMBER OF MUNICIPAL SCHOOLS EXISTING OR IN COURSE OF ESTABLISHMENT:—

	Schools.
(*a*) In 47 county boroughs ...	71
(*b*) In 130 non-county boroughs and urban districts	132
(*c*) In 30 counties ...	36
Total number of municipal schools in England	239

This number does not include—(1) those voluntary technical schools which will probably become municipal institutions in the near future, viz. the schools in three county boroughs and three non-county boroughs and urban districts; (2) the municipal classes, held in rented premises, in 29 non-county boroughs and urban districts.

(2) INCREASE IN ANNUAL LOCAL CONTRIBUTIONS FROM THE RATES:—

	Amount voted in 1895-6 £	Amount voted in 1897-8 £	Increase in Rate-aid. £
(*a*) In 15 county boroughs	7,488	17,429	9,941
(*b*) In 70 non-county boroughs and urban districts	6,791	15,960	9,169
In 85 localities	£14,279	£33,389	£19,110

These figures are exclusive of—(1) those relating to Sheffield, where an additional sum of 1000*l.* will be raised by rate during the current year; (2) a total sum of 29,777*l.*, which has been voted from the general rate funds of urban authorities, and applied entirely to *capital* purposes.

(3) TECHNICAL SCHOOLS ESTABLISHED, EXTENDED, ADAPTED, &c., SINCE 1889:—

	County Boroughs.	Non-County Boroughs, &c.	Counties.	Totals.
Number of schools established...	42	89	32	163
" " in course of establishment	12	56	4	72
" " extended or adapted ...	14	46	—	60
" " transferred, purchased, or presented...	29	43	—	72

(4) PROVISION OF SITES FOR TECHNICAL SCHOOLS:—

	County Boroughs.	Non-County Boroughs, &c.	Totals.
(*a*) Sites *purchased* by the local authority ...	20	44	64
(*b*) Sites *given* by the local authority ...	8	17	25
(*c*) Sites *presented* by private individuals or Trustees ...	7	28	35

(*d*) Sums *involved* in the acquisition of sites { in 23 county boroughs ... £122,528; in 66 non-county boroughs and urban districts ... 55,214

Total for 89 localities £177,742

(5) CAPITAL EXPENDITURE UPON TECHNICAL SCHOOLS SINCE 1889:—

	Total sum involved. £	No. of localities.	No. of buildings
(*a*) County boroughs ...	1,351,193	50	69
(*b*) Non-county boroughs and urban districts	826,376	166	172
(*c*) Counties ...	112,853	22	26
Totals ...	2,290,422	238	267

To this sum an amount of 50,229*l.* should be added as representing the value of sites for technical schools presented by local authorities, Trustees, and private individuals in 18 localities, and included under section (4) of this summary; an aggregate amount of 2,340,651*l.* is thus shown as having been absorbed by the establishment of technical institutions in England from the year 1889. It should, however, be pointed out that the figures under (*c*) do not include the sums spent by the County Councils of Cambridgeshire, Lancashire, Warwickshire, and the East, North, and West Ridings of Yorkshire upon their municipal institutions.

Of the funds dealt with above, it is only possible to give the derivation of a sum of 1,854,036*l.*, which is apportioned among the different authorities as follows:—

	County Boroughs. £	Non-County Boroughs, &c. £	Counties. £	Totals. £
Loans ...	657,183	259,047	27,350	943,580
Donations and subscriptions, and Trust funds ...	309,716	178,436	13,567	501,719
Residue grant ...	167,642	92,366	71,936	331,944
Science and Art Department's grants	11,101	35,915	—	47,016
Lump sums from rate fund ...	18,036	11,741	—	29,777
	£1,163,678	577,505	112,853	1,854,036

In order the more easily to grasp the significance of these figures and to facilitate comparison, it may be well to present the following table of percentages:—

	County Boroughs. Per cent.	Non-County Boroughs, &c. Per cent.	Counties. Per cent.
Loans ...	$56\frac{1}{2}$	45	$24\frac{1}{4}$
Donations and subscriptions and Trust funds ...	$26\frac{3}{4}$	31	12
Residue grant ...	$14\frac{1}{4}$	16	$63\frac{3}{4}$
Science and Art Department's grants and lump sums from rate fund ...	$2\frac{1}{2}$	8	—
Per cent. ...	100	100	100

From this table it will be seen that, while the largest proportion of capital expenditure in the county and non-county boroughs, &c., is met by loans, the main source of supply of the County Councils is still the Residue grant. The extent of the assistance rendered by voluntary effort is also clearly indicated, as well as that given by the Science and Art Department; the smaller urban districts appear to have received the largest contributions from these two sources.

THE BRITISH ASSOCIATION.

BRISTOL MEETING.

SECTION K (BOTANY).

OPENING ADDRESS BY PROF. F. O. BOWER, SC. D., F.R.S., PRESIDENT OF THE SECTION.

SHORTLY before we met last year in the hospitable Dominion of Canada, two biologists, whose work relates to the questions I propose to discuss to-day, passed away. In both cases their services to science had received honourable recognition in this country. Johannes Japetus Smith Steenstrup, who had been for more than thirty years a foreign member of the Royal Society, died June 20, 1897, at the advanced age of eighty-four; Julius von Sachs, also a foreign member of the Royal Society, died May 29, 1897, aged sixty-five.

The former of these, a zoologist, was probably best known in this country for his work on "Alternation of Generations," a translation of which was published by the Ray Society in 1845. The title-page describes the phenomenon as "a peculiar form of fostering the young in the lower classes of animals." Botanists should remember that this term "alternation," which they often use in a sense peculiarly their own, was originally applied to the course of development in certain animals, by Chamisso in 1819. The first general statement of the subject from the zoological side was by Steenstrup in the work already named; even there no mention is made of such phenomena in plants, until the concluding paragraph, where there is an allusion in very general terms to the course of events in the life of seed-bearing plants. But when we remember that it was only in 1848 that Suminski discovered the antheridia and archegonia borne upon the prothallus of a Fern, we see plainly that Steenstrup could not have used the term "alternation" in the sense in which it is now generally applied to plants. The interest for us as botanists will therefore be that Steenstrup suggested in his work on alternation in animals how in the life of plants successive phases exist, and that these are comparable to those which he described in many animals.

The work of Sachs, on the other hand, has influenced every one of us. Some, including myself, have had the great advantage of his direct personal guidance; all must have derived pleasure as well as profit from his writings. I shall not here attempt any general summary of the achievements of this great man, for that has been done efficiently by the scientific press at large. I shall merely allude to one feature of his work, viz. the style of its presentment to the reader. He was always clear, usually concise. He was, in addition to his power as an investigator, a master with the pencil, as well as with the pen. It was this combination of qualities which made him the great text-book writer of his time. Never perhaps has a volume more fairly reflected the position of a science at the moment of its publication than did that of Sachs. It resembles the work of a snap-shot camera, and, like any instantaneous photograph of life in motion, it has fixed and perpetuated awkward positions. The morphological system of the time was stiff and unpromising; the text-book accurately depicted this, but it did not suggest or anticipate future developments; it did not bear the softened image of a longer exposure; it presents to us the angular attitude of a moment.

The powers of Sachs as a writer found their best scope in his "History of Botany," a work which will always retain its value as a masterly exposition of the results of very wide reading, arranged with a literary skill which is unfortunately rare among scientific men. I lay stress upon this power of Sachs as a writer, apart from his record as an investigator, because he was strong where so many of us are weak. The truth is that little effort is made by men of science to use a concise and transparent style; for the most part we write by the aid of such instincts as nature has given us; few cultivate composition. But it should, I think, be impressed upon the young aspirant that, when he writes, it is one of his first duties to consider his readers' convenience; he must use all endeavours to convey forcibly the result of his inquiry, but to make the least possible demand upon the patience of his readers. I should like to see certain papers selected as models of construction, to be studied as such by all candidates for our higher degrees; we should naturally include in the list those of the best masters of style in foreign languages, and among them would rank the late Julius von Sachs.

THREE PHASES OF MORPHOLOGICAL STUDY.

It will be in your memory that the Address of last year's Sectional President was largely devoted to branches of our science which touch the material and economic interests of man. It was pointed out to us how certain fungal diseases diminish agricultural profits to an extent which may be estimated in millions of pounds yearly. Beneficent microbes were also mentioned, such as those which govern the aroma and maturing of butter and cheese; these and many others, the study of which lies properly within the province of botany, affect not only the health, but, at the most varied points, the comfort and prosperity of mankind.

It is unnecessary for me to dwell further upon these matters, or to urge again the utilitarian argument for the proper support of botany. I propose, on the other hand, to invite your attention this morning to the Morphology of Plants. This is a department of science pure and simple. The results which it brings have not, and cannot be expected to have, any money value in the markets of the world. The present time is one of unusual bustle and change in morphology, consequent upon the discovery of new facts and the introduction of new methods. The development of the study may be divided into three periods, we ourselves standing upon the threshold of the third. The earliest phase was that of description and delineation of what might be observed of the mature form of plants; this includes the work of the herbalists and of the earlier systematists, who thus furnished the basis for classification. It is true that the mere description was enriched at times by comparisons made, but these often took a capricious form, as is shown by the many curious allusions which still survive in the nomenclature. Erasmus Darwin satirised the imaginative comparisons indulged in by early writers in his "Loves of the Plants"; an instance of this is seen in his lines referring to the legendary organism, half animal, half plant, suggested by the peculiar form of *Dicksonia* (*Cibotium*) *Barometz*:—

> "Cradled in snow and fann'd by arctic air
> Shines, gentle Barometz, thy golden hair.
> Rooted in earth each cloven hoof descends,
> And round and round her flexile neck she bends;
> Crops the gray coral moss, and hoary thyme,
> Or laps with rosy tongue the melting rime.
> Eyes with mute tenderness her distant dam,
> Or seems to bleat, a *Vegetable Lamb*."

The tendency to comparison thus already perceptible asserted itself strongly in the next phase of our study, to which it gave its character. And now the need arose for observing development; this was initiated by Schleiden, and carried to a triumphant climax by Hofmeister. Passing from the hands of these pre-Darwinian to those of post-Darwinian writers, the comparisons, while remaining virtually the same, received a new significance. Observers now pushed their inquiries into the details of anatomical structure and development, and in many cases attached an importance beyond what is justifiable to minute similarities or differences of cell-cleavage. Thus what might be called "cellular morphology" became a feature of the period. It has, however, been in a measure discredited by the excessive zeal of some of its votaries, who drew large conclusions from slight facts; a salient example of this is furnished by studies concerning segmentation of the ovum. But we must not assume that because it has been pursued indiscreetly, the study of segmentation is effete; there is still scope for valuable observation, which will bear a reasonable burden of argument; though conclusions from such a source must be compared with those derived from other data, and a due estimate of them must be made accordingly.

Morphology has lately passed to a third stage—that of experiment—with a view to ascertaining the effect of external agencies in determining form, and the limits of variability under varied circumstances. Development of itself shows only how a part originates; it does not demonstrate what it is, nor what it may become under special conditions. This new and growing phase of experimental morphology, together with comparison

from the point of view of descent, now tends to supersede the formal morphology of the second period, which in many minds implied or assumed ideal types or creative plans. It has become a general view that the facts of morphology are but the stereotyped facts of physiology, form being determined by function, but under the check of heredity. This third experimental phase of the study of plant form is directed, as it were, to the very setting of the types, before the stereotype plate is cast. We watch nature's compositor at work, but we also ascertain that the plate itself, after it is cast, is much more plastic than some of us had thought.

These three phases of morphological inquiry have naturally overlapped one another; we recognise, however, that first description, then formal comparison, and now experiment, have been the leading features in morphological investigation during these successive periods.

HOMOLOGY.

The ideal aimed at in the study of the morphology of plants is to trace their real relationships and mode of origin, on the basis of the widest observation—in short, to reconstruct the evolutionary tree. In order to make comparison possible, or at least manageable, a terminology is necessary, and this not only of the plants themselves, but also of their parts. We may for the moment leave on one side that summing up of morphological opinion represented by the systematic arrangement of plants in a taxonomic system. I propose to-day to discuss not the classification of plants, but the classification of the parts of plants, their grouping according to their *homology*. And here I use a word which is probably explained to every class of elementary students; it is one of those terms a meaning of which is indeed revealed to the babes of the science, while those who teach are not at one as to its definition. We need not enter now into the various opinions which have been held on this point, nor need we make any antiquarian research into the introduction or early use of the word *homology*: it will suffice to state that it was already firmly established in the science before views as to descent gave it any intelligible meaning. We speak of the homologies recognised by Hofmeister, but it should be remembered that their great discoverer did not put an evolutionary interpretation upon them. Sachs points out in his history how "the theory of descent had only to accept what genetic morphology had already brought to view." Nevertheless, much remained ingrained in the very texture of the science which was incompatible with evolutionary thought. This was so even in the text-book of Sachs itself. The categories of root, stem, leaf, and hair are there laid down, and the parts classed under these several heads were held to be *homologous*. In their definition all those characters which refer to function were put aside, the definitions relating to origin and relative position; the reproductive organs were grouped with the rest, with the result that these parts were described as bearing a varying morphological value. But this purely formal morphology is now dead; it long survived a mere passive belief in evolutionary views, but their active practice has strangled it. The first step towards emancipation was the recognition of sporangia as parts *sui generis*. Eichler, agreeing with Braun and Strasburger, found it "highly probable according to the theory of descent" that such a structure as the ovule has universally the same morphological dignity. It remained for Goebel to make the general statement that sporangia stand in a category by themselves, and are probably not the result of modification of any vegetative part. It was in this way that the phylogenetic factor was first asserted as bearing on a question of importance in the morphology of plants. Adherents of descent no longer passively accepted the direct results of investigation; they began actively to check and control the interpretation of them; but this position was not attained till more than twenty years after the publication of Darwin's "Origin of Species." Since then, however, views as to descent have taken an increasingly important place in the province of morphology, till at the present moment a far-reaching comparison of allied forms, assisted by experiment, is the most potent instrument in the hands of the morphologist.

But various writers admit in varying degree this factor of comparison as controlling other considerations. There is indeed a wide range of difference on this point. I will cite only two extreme views. On the one hand is the view of Strasburger, which he enunciated so early as 1872. The enthusiasm for evolution in the Jena school found its botanical expression in the aphorism, "The highest problem of morphology is to explain the form of plants, but this problem can only be solved genealogically." This statement is repeated in a more definite form in Strasburger's text-book: "Phylogeny is thus the only real basis for morphology."

At the other extreme is the method of physiological organography put forward by Sachs in his Lectures. I am aware that he subsequently modified his views; I merely quote the system which he propounded in 1882, as being the antithesis to that of Strasburger. For in the physiological organography descent is hardly taken into account at all; parts which are plainly of distinct origin by descent are classed together. This organography of Sachs, though introduced with all its author's charm of style, never convinced the botanical world, for it treated plants too much as the creatures of present circumstance. It may be taken as illustrating the extreme reactionary swing of the pendulum from the non-physiological attitude of the formal morphologists; a protest against the exclusion of function from the morphological arena. The protest was salutary, but its form was extravagant.

Let us now consider whither "phylogeny, as the only real basis of morphology," may lead us. Let us take as our provisional view that *homology* in the strictest sense implies repetition of individual parts, in successive generations, just as the hand of the child repeats in position and qualities the hand of the mother. Though among seed-bearing plants, for instance, this repetition may apply for the plant-body as a whole, it will be at once apparent that such repetition as regards the individual is found in comparatively few cases in plants. The continued embryology of all the higher forms, the indefinite number of the parts successively produced, and the variety in detail of their arrangement show that in the strictest sense repetition of individual parts cannot be traced. In a pan of seedlings of the Sunflower, raised from seed of the same parent, the cotyledons in all cases may be regarded as homologous in the strictest sense, as they correspond in origin, number, position, and form to like parts in the parent. In a similar way the first root of the seedling appears to be individually identical with the first root of the parent, or of any other seedling of the batch. In those plants in which a foot or suspensor is present occupying a constant position with regard to the parts of the embryo, it will not be doubted that within near lines of affinity the foot in any one specimen corresponds to that of any other. The exact repetition which is thus found to exist may be regarded as the most complete type of homology.

Starting from this repetition of individual parts in plants nearly related, there is a divergence by gradual steps in two directions: Firstly, in the individual plant, where the later formed parts may assume forms and positions which may even raise a question of their essential correspondence. Thus in the batch of Sunflower seedlings there may be a varying number of leaves, with varying transition from the decussate to the alternate arrangement, intervening between the cotyledons and the capitulum. As they vary in number and position these cannot in the strictest sense be accepted as individually comparable, each to each by descent—the lineal representatives of like individual parts in the parent. The lateral roots also, though all essentially similar, do not correspond each to each, either in number or in position.

Again, to go a step further, a Fern prothallus produces antheridia and archegonia; their number and position are not uniform; by conditions of culture we have them under control, and can induce antheridia only, or we can induce a formation of archegonia upon the upper surface, where they are usually absent. Plainly these cannot be held severally as the exact representatives of like individual parts in a previous generation. Another exceptional, but most interesting, case is that of *Aspidium anomalum*, Hk. and Arn., which Sir William Hooker remarks is possibly an abnormal form of *Aspidium* (Polyst.) *aculeatum*, Sw. In this Fern the sori, instead of being all on the lower surface, as in allied Ferns, are often upon the upper surface of the leaf. There is no sign of torsion to explain the anomaly, while the sori themselves present no structural peculiarity except that they are sometimes quite destitute of indusium. There has doubtless been a transfer of developmental capability from the usual position of the sori to the anomalous one. In case of such transfers as these we do not doubt that the parts in question are to be ranked as comparable to those in the normal position; we contemplate here,

as in the case of the Sunflower leaves, an essential correspondence, but not an individual repetition of the parts, and we learn that parts thus essentially corresponding to one another may be transferred to unusual positions.

Secondly, in plants more or less nearly related, those which are less akin may show so slight a similarity in detail that again questions of the essential correspondence of the parts may arise. Within nearer circles of affinity these questions will affect only the appendages of minor importance, which show less constancy of occurrence and arrangement, such as emergences and hairs; but in case of plants less nearly akin the degree of correspondence of the larger members may become a matter of debate. Take, for instance, the three great phyla of living Pteridophytes, the Ferns, Equiseta, and Lycopods. While the sporophyte as a whole in each of these may be accepted as homologous by descent with that of the others, the question as to the true correspondence by descent of the leaves must still be open for discussion. It is a tenable view that the three phyla arose separately from a non-foliar ancestry, and that the assumption of a foliar development, having in each case a different habit, and a different relation to the sporangia, led to the distinctiveness of the three stocks. Opinion on the point of homology by descent of the leaves of these Pteridophyta must at present remain in suspense; but the case is different with the leaf of Pteridophytes as compared with the leaf of Bryophytes: unless the whole morphological system of the time be in error, we shall be right in maintaining that these foliar developments have been distinct in origin from the first.

Now all the foliar parts above quoted would in a system of merely formal morphology fall into the category of "leaves." But if phylogeny be accepted as the only real basis of morphology, we must be prepared to split up the category based on mere time, place, and mode of origin, and to recognise in some cases repetition of individual parts; in others essential correspondence, but not individual repetition, owing sometimes to transfer of developmental capability; in other cases again, a possibility of distinct origin by descent not actually proved; and lastly a reasonable certainty of distinct origin. The practical question for the morphologist is, having recognised these facts for himself, how is the matter to be best made intelligible to others?

A reconsideration of the term "homology" will thus be necessary; is it to be applied equally to such parts as are connected by lineal descent, and also to those which we have good reason to believe have resulted from parallel development in quite distinct phyla? Or, to put a finer point upon our inquiry, are we to distinguish in any way the cases of "individual repetition" from those of "essential correspondence"? In the latter case I think no good end would be served at present by accentuating this distinction by terms: the steps of divergence are so slight and gradual. None the less should it be clearly borne in mind that comparisons of parts commonly ranked as homologous in the plant body are based on a less complete individual correspondence than that of parts usually compared in the animal body.

But the case is different in dealing with parallel developments, and some doubt arises whether parts which probably, or it may be certainly, have arisen by separate evolutionary sequence in distinct phyla are to be classed as homologous in the same sense as those directly related by descent. This question was long ago taken up on the zoological side by Prof. Ray Lankester, and it was shown that the old word "homology" covered two things recognised as distinct from the point of view of descent. He defined as *homogenous* "structures which are genetically related, in so far as they have a single representative in a common ancestor." On the other hand, "when identical or nearly similar forces or environments act on two or more parts of an organism which are exactly or nearly alike: further, if, instead of similar parts in the same organism, we suppose the same forces to act on parts in two organisms, which parts are exactly or nearly alike, and sometimes homogenetic, the resulting correspondences called forth in the several parts in the two organisms will be nearly or exactly alike. . . . I propose to call this kind of agreement *homóplasis* or homóplasy." Now this distinction of terms requires also to be observed in plant-morphology, and I am surprised that it has never yet been adopted by botanists, though we have long recognised cases of parallel development. I do not propose now to spend time in assigning these terms to familiar cases: but to take the examples already cited, the leaf of a Fern would be homoplastic, though not homogenetic with the leaf of a Moss; or, taking examples from plants more nearly akin, it would appear possible that the leaves of the three distinct phyla of living Pteridophytes show merely homoplasy not a true homogeny.

The successive foliage leaves of most plants are assumed in the individual to be the result of a mere repetition of development. But it is quite a possible view that in the plant-body (as is contemplated in the animal in those cases of "serial homology" which Lankester recognises as homoplastic) homoplasy may have had a place. We must inquire whether all those structures which we designate "leaves" have actually been the result of a development identical, or at least essentially similar as regards their origin in the race. The problem is, given a plant with numerous leaves of various form and function, to unravel the real story of their evolution. Two distinct factors may be contemplated as possibly occurring even in the individual, viz.:

(1) *Homogeny* of genetically related parts, with or without repetition of the parts formed.

(2) *Homoplasy*, an origin of two or more distinct categories of parts, not genetically related, on the same organism.

Working upon either of these, and thus complicating the problem by obliterating such distinctions as may have existed at first, may be the phenomenon of *metamorphosis*. This has lately received its evolutionary definition at the hands of Prof. Goebel, as restricted to those cases where there has been an obvious change of function. We see how change of function accounts for various forms of leaf in certain cases; but it does not follow that all leaf-forms on the same plant were so produced, by metamorphosis of a single original type.

The Lycopodineae are particularly interesting in illustration of this point. It appears probable that *Phylloglossum* is a more primitive type than other living Lycopods; it has two kinds of leaf, the protophylls borne in irregular number and arrangement on the protocorm, and the sporophylls of different form from these, and arranged regularly on the strobilus: commonly there are no intermediate steps between them. This condition in a plant, which on general grounds of comparison we believe to be primitive, is certainly interesting, and we shall ask whether the two types of leaf have not arisen by distinct evolutionary sequence? In the genus *Lycopodium* there are certain species, such as *L. Selago*, which show alternately sterile and fertile zones; examining the limits of the sterile zones, we find at the base of each leaf an atrophied sporangium, similar in position to that borne by a sporophyll. When we compare this condition with that of *Phylloglossum* it appears probable that the successive zones are the result of a metamorphosis of a strobilus, which had a continuous apical growth, and unlimited repetition of sporophylls, but that some of these suffered atrophy of their sporangia, with the correlative effect of a larger vegetative development. A differentiation of the strobilus thus results in the plant as we see it, a production of foliage leaves by sterilisation of sporophylls. Recognising this, some may suggest that the protophylls originated in the same way. It is possible that they did; but it is equally possible, and, in view of the peculiar case of *Phylloglossum*, I think more probable, that in these plants we have an example of homoplastic development of parts distinct as to descent, while the limits of the two still evident in *Phylloglossum* became obliterated in the more complex case of *Lycopodium*. The proof of the point will be difficult or even impossible, but the eyes of botanists should certainly be open to recognise such individual homoplasy, should it occur, and to inquire whether it has really had a place in plant-development.

Returning now to homoplastic development in distinct groups of plants, the morphology of the *foot* provides interesting material for comparison, and especially so since there is no question of repetition here; for the comparison is between parts of which only one appears on each individual plant.

The term foot has been applied to that part of the embryo in Pteridophyta which serves to connect it physiologically with the prothallus; the term has also been used for the base of the seta in Bryophytes. Parts performing a similar function, but not referable, as in other Phanerogams, to the metamorphosis of cotyledons, are also found in *Gnetum* and *Welwitschia*.

In the Bryophyta what is usually called the foot is no definitely specialised structure; it is merely the absorbent base of the seta. It would appear probable that in the Bryophyta a true homogeny holds in all cases, as the requirement for it will have been

uniform; and its basal position is also uniform, though some difference of detail does appear in the relation of this absorbing body to the first segmentation of the embryo.

In the Pteridophyta it is exceedingly difficult to be sure of the correspondence by descent of the foot in distinct types, and indeed it should not be assumed that a specialised absorbent organ was always present, though general surface-absorption will naturally have taken place in all archegoniate embryos; indeed the condition of some upright embryos is such that a foot would never have been described, were it not for comparison with other types. In *Equisetum*, *Isoetes*, *Botrychium*—all forms without a suspensor, and with an upright growing embryo—the hypobasal half of the embryo, with or without a root, is absorbent as in the Bryophyta, and is described as a foot; it is quite possible to see in them the continuation of a primitive absorbent organ. This may also be the case in the Marattiaceae, and it is specially noted by Campbell that "in *Marattia* all the superficial cells of the central region become enlarged and act as absorbent cells for the nourishment of the embryo." From such types we may imagine the more specialised foot of the Leptosporangiate Ferns to have been derived by a localisation of the absorbent function on one side only, which would be a natural consequence of the embryo taking the prone, in place of the vertical position.

A different course of events probably occurred in the Lycopodineæ. I am disposed to think that here the suspensor represents nothing more than a specialised part of the primitive absorbent organ; this seems to be indicated by the details as shown in Treub's figures of *L. cernuum* and *L. Phlegmaria*, in which the suspensor is continuous with the foot. But what is then the "foot" of *Selaginella*, which is quite apart from the suspensor, the root intervening? On this point I think we obtain light from *Welwitschia* and *Gnetum*, for in these we see an absorptive organ formed at a comparatively late period; and it corresponds in position and function, though not in time of origin or details of structure, with that of *Selaginella*. I conclude that the "foot" of *Selaginella* is probably a later formation, not comparable as regards descent either with the foot of *Lycopodium*, or with the "feeder" of *Welwitschia* or *Gnetum*. The latter are plainly of recent independent origin, as comparison shows, and their actual position is defined according to the position of the seed in germination. Probably, then, there is homoplasy in such cases, not true homogeny.

Similarly with such structures as the pinnae, stipules, indusium, corona, and still more so with such inconstant bodies as emergences and hairs; when we speak of the "homologies" of these parts it is rarely the *homogeny*, or identity by descent, which we mean to express; usually it is only *homoplasy*, a comparison of parts similar, it may be, in form and position, or even in development and function, though not shown to be comparable by descent.

ALTERNATION.

But the questions above discussed are mere matters of detail, compared with that great enigma of the alternation of generations in green plants, or of alternation at large. This is, after all, a question of degree of homology, not now of the parts only, but of the whole plant or "generation." How this greatest of all adaptations was really initiated, we cannot expect to bring to the point of demonstration; at best we can only venture opinions of probability. Still this discussion commands at present more widespread interest among botanists than any other in the sphere of plant morphology.

There was a time when the attempt was made to reduce all plants to one scheme as regards their life-cycle, a method which not only prevented elasticity of theory, but was responsible for some unfortunate comparisons. It was characteristic of the period when the text-book of Sachs reigned supreme; we find it there definitely laid down that "the doctrine of alternation has the object of reducing to one scheme the main phases of the life of all plants which bear sexual organs." But the controversy between Pringsheim and Celakovsky had, as one of its results, the recognition of various types of life-history, not of one scheme only. The tendency at present is towards the opposite extreme; the frequency of the parallel developments now recognised has led some to accept a comprehensive polyphyletic view as regards alternation, and wherever difficulties of comparison arise, to take refuge in the plausible suggestion that the organisms compared represent altogether distinct lines of descent. But the view which should be confidently upheld, is that even where this may actually be the case useful comparisons may yet be made; and that the method of progress within one phylum may illustrate the probable mode of progress in another. The green Algæ may thus throw light upon the probable origin of the sporogonium in the Bryophytes, though they may in no sense be in the line of their descent; the Bryophytes may suggest valuable ideas for the comparative study of the Pteridophytes, though they may not represent their actual ancestry.

It is the alternation as seen in these green plants that I propose to discuss. Writers have distinguished various types of alternation, including under the term divers modes of "alternation of shoots"; and it should be remembered that this was the original sense of the word alternation as applied by Steenstrup. But gradually the issue in the case of green plants has been simplified, and the question now centres round that alternation of phases which some of us describe as "antithetic," while others believe the phases to be really "homologous" as regards their origin.

Briefly put, the question is, How was the first start made? Has the neutral generation or sporophyte been the result of change of any other part of the sexual generation than the zygote itself? If so, the alternation is of *homologous* generations; if not, then the alternation is what is styled *antithetic*. The whole discussion is like a purely historical inquiry, but with the minimum of documentary evidence; for on this point the fossils give scanty help. In the absence of more direct evidence we are thrown back on other aguments, such as those based on comparison of normal specimens, and secondly upon the study of abnormalities. I shall not attempt to treat the matter exhaustively; it will, however, be necessary for me to deal with certain points in the discussion which were raised in the able address of Prof. Scott at Liverpool. He there restated Pringsheim's view of homologous alternation as against the antithetic. I propose now to consider three matters which I think are most material to the discussion, viz. (1) the bearing of the Algae and certain Fungi on the question; (2) the comparison from the Bryophyta; and (3) the argument from abnormalities.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—At the conjoint examination for entrance scholarships, just completed, the following awards have been made in Natural Science. At Pembroke College: Scholarship, G. H. Delf, Camberwell Grammar School, 40*l*. At Gonville and Caius College: Exhibition, M. M. L. Rittenberg, Tonbridge School, 30*l*. At Jesus College: Scholarship, J. Hewitt, Derby School, 40*l*. At Christ's College: Scholarship, C. H. B. Epps, City of London School, 40*l*.; exhibition, R. B. S. Sewell, Weymouth College, 30*l*. At St. John's College: Scholarship, G. C. E. Simpson, Mill Hill School, 60*l*.; Lupton and Hebblethwaite Exhibition (open *pro hac vice*), J. F. Hough, Mason University College, Birmingham; Johnson Exhibition (open *pro hac vice*), B. E. Mitchell, Brighton Grammar School. At Emmanuel College: Scholarship, H. U. B. Banham, Ipswich Grammar School, 40*l*.; exhibition, A. C. H. Rothera, Market Bosworth School, 30*l*. Clare College: Scholarships of 60*l*. to E. B. Bailey, Kendal Grammar School, and W. Cartwright, Middlesburgh Grammar School. Trinity College: Minor Scholarship of 75*l*. to C. S. Coles, University College, London; Exhibitions of 40*l*. to J. Frame, Mason College, Birmingham; C. W. Hutt, St. Paul's School, London; T. C. James, Aberystwyth University College; H. Lambert, Perse School, Cambridge.

Mr. F. G. Hopkins has been appointed University Lecturer in Chemical Physiology.

The degree of LL.D. will be conferred on Lord Kitchener of Khartoum on November 24.

The Clerk Maxwell Studentship in Experimental Physics will be vacant at the end of this term. Candidates, who must have worked in the Cavendish Laboratory, are to send their names to Prof. Thomson by December 9.

It is proposed that Advanced Students shall be admitted to Part II. of the Mechanical Sciences Tripos, and that for the B.A. degree they shall be required to attain the standard of the Second Class at least.

The General Board of Studies have proposed a scheme for the establishment of an Allen Research Studentship under the

bequest of the late A. W. G. Allen. The studentship is of the value of 250*l.*, is tenable for one year, and is open in alternate years to students proposing approved courses of research in (1) literary subjects, or (2) scientific subjects.

Seventy-five candidates have presented themselves during the past year for the Sanitary Science Examination. Of these thirty-nine were successful in obtaining the University diploma in Public Health.

The Engineering Laboratory Syndicate have lost no time in proposing a plan for the Hopkinson Memorial Building. The new wing will adjoin the present laboratory, and provide a lecture-room, three laboratory-rooms, and small rooms for students engaged in research. For the completion of the plan some 500*l.* will be required, in addition to the 5000*l.* generously given by Mrs. Hopkinson and her children. It is expected that the building will be ready for occupation in October 1899.

Mr. W. N. Shaw, F.R.S., was on November 10 appointed Assistant-Director of the Cavendish Laboratory for one year.

IN Berlin the flowers gathered in the town gardens are placed in the municipal schools for the purpose of furthering the study of botany. Arrangements have now been made by the London School Board, and will come into operation in April next, whereby a gardener will collect, pack, and forward to the schools of the Board botanical specimens and flowers, budding plants, leaves, &c., required for teaching botany or for object-lessons, or for the combination of drawing and object-lessons.

IT is expected (states the *Athenaeum*) that the London University Commission will commence its sittings this month. Mr. Bailey Saunders, the secretary, has been collecting information in Germany, especially concerning the organisation of higher commercial education, which will be made an important element in the newly constituted university, with the co-operation, it is hoped, of the London County Council. It is probable that the headquarters will be removed from Burlington Gardens. Christ's Hospital is talked of as the new site.

THE Calendar of the Imperial Tientsin University for the year 1897 has been received. The University was established towards the end of 1895, and its faculty includes several graduates of colleges in the United States. Mr. C. D. Tenney is the president, Prof. Oliver C. Clifford occupies the chair of chemistry and physics, Prof. E. G. Adams the chair of civil engineering, and Prof. N. F. Drake the chair of mining. Most of the tutors and teachers are natives of China. It is announced that last year his Excellency Li Chung-ta'ng showed his good will towards the University by a present of a 4-inch telescope, a phonograph, and several things for the physical laboratory.

ALDERMAN JOHN HOPKINSON, the members of his family, and near relatives, have offered to the Owens College, Manchester, in memory of the late Dr. John Hopkinson, a gift of 1000*l.*, to cover the expense of building the dynamo house connected with the new physical laboratory. It is hoped that by additional contributions from friends who desire to see a suitable memorial of Dr. Hopkinson in Owens College, where he was a student for three years, it may be possible to complete and equip the annexe containing in addition to the dynamo house a number of other rooms devoted to electrotechnics, and that the whole may be known as the "Dr. John Hopkinson Electrotechnical Laboratory."

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 11.—Mr. Shelford Bidwell, F.R.S., President, in the chair.—The discussion on Mr. Albert Campbell's paper on the magnetic fluxes in meters and other electrical instruments was resumed. Prof. Ayrton said he wished to offer some remarks on behalf of Mr. Mather and himself. The paper would, perhaps, have received more adequate discussion at the Institution of Electrical Engineers, for it was chiefly of a technical character. The importance of neutralising the effect of leads when using instruments with very weak fields, such as a Siemens' electro-dynamometer, should be emphasised. In instruments of the Kelvin-balance type where two opposed coils carry two opposed currents, the field spreads at the edges; the true "working" flux is not that directly between the coils. Mr. Campbell would have done better if he had used a long search coil wound round one of the swinging coils, forming part of a vertical cylinder. It would have been well also to have supplied some experimental proof that the astatic arrangement of the swinging coils of the Kelvin balance makes the instrument independent of the earth's field. The effect of the earth's field is of the order 0·2, so that with instruments of the Weston type, with a field of the order 1000, it was sometimes assumed, erroneously, that the readings were practically independent of the earth's H. Prof. Ayrton's own tests showed that by turning a Weston voltmeter towards different points of the compass, the errors in a particular case were far greater than might be predicted from the above ratio; the induction in the voltmeter pole-space, due to the earth's field, was much higher than 0·2; the earth's field was exaggerated by the iron pole-pieces; it was not necessary to suppose that the magnetism of the permanent magnet caused the variation. The error observed was about 0·2 per cent. in a horizontal field, and 0·8 per cent. when the field of the voltmeter was parallel to the earth's induction. Here the induction in the gap was 1200, and H = 0·2. In tests relating to the Ayrton and Perry magnifying-spring voltmeter, it was more important to know the B in the air-space *near* the iron than the B *within* the iron. Eddy currents might account for the extraordinary results obtained with the Shallenberger meter. Mr. J. H. Reeves described a method he had adopted for measuring the effect of stray fields upon ammeters and voltmeters. The instrument to be tested is first mounted on a stand and is brought under the influence of a large coil carrying a current. In this way, fields of known magnitude can be superimposed on the working field, throughout the range of the instrument, and the change of deflection due to them can be observed. From these known values, the working field can be deduced. For let the current in the solenoid of the instrument at any moment be A amperes, producing a corresponding unknown working field of magnetic force X. Then X is proportional to the solenoid current, as measured by the indications of the instrument. If a magnetic force x is superimposed on X, then x is measured by x X of A. If x is known, the working field X can be calculated from the change of deflection produced by the superposition. With Evershed ammeters, the field measured in this way was in one instrument 200, and in another 226; or about one-third of Mr. Campbell's figure (700) for the Evershed ammeter. Mr. Campbell's value of B did not represent the working field, but the field at the end of one of the fixed pieces of iron. Mr. Campbell, in reply, said he thought the theory of electrical instruments to be well within the limits of physics, and he had for that reason presented the paper to the Physical Society. The position chosen for the search coil in the Kelvin-balance tests may not have corresponded to the working flux, but it was near to the right position, and he had carefully specified the position chosen. His results as regards the Weston instrument differed from those of Prof. Ayrton, the errors he had observed for the particular ammeter used were under 0·1 per cent. The earth's field probably produced an effect different for different Weston instruments, according to the degree of saturation of the permanent magnet. In Mr. Campbell's tests, the Weston instrument did not have an iron case.—A paper by Prof. W. B. Morton, on the propagation of damped electrical oscillations along parallel wires, was then read by Prof. J. D. Everett. In a paper published in the *Phil. Mag.* for September 1898, Dr. E. H. Barton compared the attenuation of electrical waves in their passage along parallel wires, as experimentally determined by him, with the formula given by Mr. Heaviside in his theory of long waves. He finds close agreement as regards the effect of a terminal resistance, but large discrepancy in the case of the attenuation constant. Prof. Morton now investigates how far the results should be modified when it is supposed, as under actual conditions, that the oscillations propagated from the origin are damped, and that the circuit is not balanced, as in the ideal case of distortionless transmission. He finds (1) that the velocity of propagation is increased, while (2) the attenuation is increased, and (3) with infinite resistance between the ends of the wires, the waves are, as before, reflected completely with phase unchanged. As the resistance is diminished the amplitude of the reflected waves is decreased, and a phase-difference is introduced. For a certain value of the resistance the reflected amplitude is a minimum, and the phase-difference is $\pi/2$. When the resistance is zero there is again complete reflection, with the phase-difference π; *i.e.* the waves are reversed. The

result is that the reflection-factor for amplitude *seems* to pass continuously from (+1) to (−1) *without* passing through zero. Using the numbers given by Dr. Barton, it is found that the corrections to the simple theory are extremely small, so that in actual cases the damping may be ignored, and the circuit may be regarded as distortionless.—Mr. Oliver Heaviside (abstract of communication): Mr. Heaviside, using his own notation, exhibits mathematically the connection between the case investigated by Mr. Morton, of a wave-train arising from a damped source, and the standard case of an undamped source. The cause of the attenuating coefficient coming out twice as great in Dr. Barton's experimental conditions, as when the resistance is calculated by Lord Rayleigh's formula, is attributed to lack of correspondence between the experimental conditions and those of the ideal theory. For: (1) The external resistance, of unknown amount, is ignored. (2) It is not certainly to be expected that the formula in question is true for millions of vibrations per second. It may, however, be concluded from the experiments that the theory furnishes an approximation to the real resistance. (4) The magnetic vibrations to which the wires are subjected are not long-continued and undamped, as assumed by the formula. When a wave-train passes any point on a wire, its surface is subjected to an impulsion vibration lasting only a very minute fraction of a second; a vibration, moreover, which is very rapidly damped. So there is no definite resistance, and the resistance is greater than according to Lord Rayleigh's formula. (5) Perhaps, also, the terminal-reflections involved in Dr. Barton's calculations may introduce error.—The President proposed votes of thanks to the authors, and the meeting was adjourned until November 25.

Chemical Society, November 3.—Prof. Dewar, President, in the chair.—The following papers were read:—Determination of the equivalent of cyanogen, by G. Dean. By determining the quantity of potassium bromide which will react with a known weight of silver cyanide dissolved in nitric acid, the equivalent of cyanogen was ascertained to be 26·065; if the atomic weight of carbon be 12·01, that of nitrogen is 14·055.—The composition of American petroleum, by S. Young. The hydrocarbons boiling between 25° and 115° contained in American petroleum are isopentane, pentane, pentamethylene, isohexane, hexane, methylpentamethylene, benzene, isoheptane, heptane, methylhexamethylene and toluene.—The separation of normal and isoheptane from American petroleum, by F. E. Francis and S. Young. The presence of naphthenes in American petroleum renders it impossible to separate pure iso- and normal heptane from this source by fractional distillation; the impure heptane was brominated, and the heptyl bromides separated by distillation. The pure hydrocarbons were then isolated by reduction with a copper-zinc couple.—The boiling points and specific gravities of mixtures of benzene and normal hexane, by D. H. Jackson and S. Young. It is impossible to separate pure normal hexane by distilling mixtures of this hydrocarbon with benzene.—The action of fuming nitric acid on the paraffins and other hydrocarbons, by F. E. Francis and S. Young. The isoparaffins react readily with fuming nitric acid yielding nitro-compounds, but the normal paraffins are only very slowly attacked.—A composite sodium chlorate crystal in which the twin law is not followed, by W. J. Pope. In a composite crystal of sodium chlorate a four-fold axis of symmetry of the one individual was found to coincide in direction with a three-fold symmetry axis of the other; the plane (011) on the latter is parallel to the plane (010) upon the former.—Stereoisomeric bromonitro- and chloronitro-camphors, by T. M. Lowry. Nitric acid acts on bromo- or chloro-camphor with production of only one nitro-derivative in each case; on brominating or chlorinating nitrocamphor in alkaline solution, however, two stereoisomeric nitro-halogen derivatives are obtained in each case.—Camphoryloxime (camphonitrophenol), by T. M. Lowry. Camphonitrophenol is an oxime of camphoric anhydride.—The formation of ethereal salts of polycarboxylic acids, by S. Ruhemann and A. V. Cunnington.—Note on the action of light on platinum, gold and silver chlorides, by E. Sonstadt. During the action of light on wet silver chloride, a subchloride, hydrogen chloride and hydrogen peroxide are formed.—Methanetrisulphonic acid, by E. H. Bagnall. Fuming sulphuric acid acts upon diacetylbenzidine, its dichloro-derivative, α-acenaphthalide and acetanilide with formation of methanetrisulphonic acid, $CH(HSO_3)_3$.—The nutrition of yeast, by A. L. Stern. An increase of nutriment beyond a definite limit does not materially increase the amount of nitrogen assimilated by yeast, the percentage of nitrogen in the yeast, the weight of the yeast, or the amount of sugar fermented.—The yellow colouring matters of *Rhus cotinus* and *Rhus rhodanthea*. Part vi., by A. G. Perkin. Venetian sumach, the leaves of *R. cotinus*, contains myricetin; the leaves of *R. rhodanthea*, the yellow cedar of New South Wales, contain quercetin and gallotannic acid. The stems of both plants contain fisetin.—Colouring matters of the New Zealand dyewood "puriri," by A. G. Perkin. The New Zealand tree, "puriri" (*Vitex littoralis*) contains two colouring matters as glucosides; these are vitexin $C_{15}H_{14}O_7$ or $C_{17}H_{16}O_8$ and homovitexin $C_{16}H_{16}O_7$ or $C_{18}H_{18}O_8$. The former yields a penta- or hexa-acetyl derivative.—Cannabinol, by T. B. Wood, W. T. N. Spivey, and T. H. Easterfield. A number of derivatives of cannabinol are described.—Derivatives of hesperitin, by A. G. Perkin. Hesperitin combines with sodium or potassium acetate yielding crystalline compounds; the examination of these shows hesperitin to have the composition $C_{32}H_{28}O_{12}$. The azobenzene derivative and hexacetyl derivative of hesperitine have been prepared.

PARIS.

Academy of Sciences, November 7.—M. Wolf in the chair.—Preparation of lithium-ammonium, calcium-ammonium, and the amides of lithium and calcium, by M. Henri Moissan. At low temperatures lithium and calcium dissolve in liquid ammonia, forming deep blue solutions similar to those obtained from sodium and potassium. The lithium and calcium-ammoniums are more stable than the other analogous alkali compounds. Analyses showed that these substances are represented by the formulae $LiNH_3$ and $Ca(NH_3)_4$; both catch fire in contact with air at the ordinary temperature. —Remarks by M. Guntz relating to the preceding communication.—Preliminary note on the presence of free hydrogen in atmospheric air, by M. Armand Gautier. Air taken from the open sea or from mountains at high altitudes is very free from combustible hydrocarbons, traces of which are always present in the air of towns. The pure air, however, contains small quantities of free hydrogen amounting to about 11 to 18 c.c. per 100 litres, about one-half the carbonic acid present in the same air.—Comparison between the methods of Lagrange and Gauss for the resolution of entire numbers of indeterminate equations of the second degree, by M. de Jonquières.—Effects of the section of the nerves of the *sphincter ani* on the functions, physiological and anatomical properties of this muscle, and on the organism in general, by MM. S. Arloing and Edouard Chantre. If the muscle is completely isolated from the spinal column, real incontinence does not necessarily follow, the elasticity of the sphincter being sufficient to cause the expulsion of the faeces and urine.—On the genesis of epithelium, by MM. Armand Sabatier and Étienne de Rouville. It is generally admitted that epithelium is always capable of regenerating itself, and that it borrows nothing from the neighbouring tissues. This is contrary to the results obtained by the authors, who find that in many cases the underlying conjunctive tissue also takes an active part in this regeneration.—Observations on the sun, made at the Observatory of Lyons during the first quarter of 1898, by M. J. Guillaume.—Geodesic, magnetic, and astronomical surveys of Madagascar, by M. P. Colin.—On the convergence circle of some series, by M. Lean.—On stability, by M. J. Andrade.—Hertzian telegraphy without wires between the Eiffel Tower and the Pantheon, by M. E. Ducretet. The space over which the signals were transmitted was about four kilometres, and the clearness of the record showed that this distance could be considerably increased.—On the compound winding of alternators of constant voltage, by M. Maurice Leblanc. An alternator constructed on the principles here laid down was found to have a very constant voltage, even when changed rapidly from no load to full load. The residual magnetism is sufficient to render the dynamo self-exciting.—Contribution to the study of the boric ethers. Properties of triethyl borate, by M. H. Copaux. Chlorine gives trichlorethylether, $CH_2Cl_2.CHCl.O.C_2H_5$; sodium ethylate in absolute alcohol gives a precipitate of $BNa(OC_2H_5)_4$.—Combinations of phenyl-hydrazine with the halogen salts of the alkaline earth metals, by M. J. Moitessier. A description of the preparation of $CaBr_2.3H_2O.4C_6H_5N_2H_3$; and $SrI_2.4C_6H_5.N_2H_3$.—Estimation and detection of gelatine in gums and food substances, by M. A. Trillat. The aqueous solution of the gum is treated with formaldehyde. The gelatine is rendered insoluble.

and can be weighed after thorough washing by decantation. Test experiments gave results within one per cent.—The culture of some lower organisms in modified sea water, by MM. P. Duflocq and P. Lejonne. Several pathogenic organisms can become accustomed to grow in a medium containing sea water, also certain moulds (*Aspergillus niger*, *Muguet*, *Actinomyces*).—Action of the bacterium of sorbose on the aldehydic sugars, by M. Gabriel Bertrand. Arabinose, dextrose, and galactose are converted by the action of the sorbose bacteria into arabonic, gluconic, and galactonic acids respectively.—Instantaneous submarine photography, by M. Louis Boutan. In the earlier attempts at submarine photography, at least half an hour's exposure was required. The apparatus has now been so far improved that photographs have been taken of fish at distances at 1·5 to 2 metres from the lens, without any artificial light being necessary.—The post-larval stages of *Arenicolae*, by M. Pierre Fauvel.—The cephalic eyes in Lamellibranchs, by M. Paul Pelseneer.—On the Chamydomonadineae, by M. P. A. Dangeard.—On some new facts in the geology of the Dauphiny Alps, by M. W. Kilian.—On some lakes in the Eastern, Upper, and Lower Pyrenees, by MM. André Delebecque and Etienne Ritter.—Barometer movements on the meridian of the moon, by M. A Poincaré.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 17.

ROYAL SOCIETY, at 4.30.—Further Note on the Sensory Nerves of the Eye-Muscles: Prof. Sherrington, F.R.S.—Further Observations on the Effects of Partial Thyroidectomy: W. Edmunds.—Contributions to our Knowledge of the Formation, Storage, and Depletion of Carbohydrates in Monocotyledons: J. Parkin.—An Experiment in Search of a Directive Action of One Quartz Crystal on another: Prof. Poynting, F.R.S., and P. L. Gray.—The Electrical Conductivity and Luminosity of Flames containing Vaporised Salts: Prof. Smithells, H. M. Dawson, and H. A. Wilson.

LINNEAN SOCIETY, at 8.—On some Spiders from Chile and Peru, collected by Dr. Platte of Berlin: F. Pickard Cambridge.—The Botanical Results of a Journey into the Interior of Western Australia; with some Observations on the Nature and Relations of the Desert Flora, and on the Probable Origin of the Australian Flora as a whole: Spencer Le M. Moore.

CHEMICAL SOCIETY, at 8.—Preparation of Hyponitrite from Nitrite through Oxyamidosulphonate: Dr. E. Divers, F.R.S., and T. Haga.—(1) Absorption of Nitric Oxide in Gas Analysis; (2) Interaction of Nitric Oxide with Silver Nitrate; (3) Preparation of Pure Alkali Nitrites; (4) The Reduction of an Alkali Nitrite by an Alkali Metal; (5) Hyponitrites: their Preparation by Sodium or Potassium and Properties: Dr. E. Divers, F.R.S

FRIDAY, NOVEMBER 18.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Production of Liquid Air, and its Application to Chemical and other Industries: Cecil Lightfoot.

QUEKETT MICROSCOPICAL CLUB, at 8.

MONDAY, NOVEMBER 21.

SOCIETY OF ARTS, at 8.—Acetylene: Prof. Vivian B. Lewes.

IMPERIAL INSTITUTE, at 8.30.—The Stalactite Caves of New South Wales: Frederick Lambert.

TUESDAY, NOVEMBER 22.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: Electrical Transmission of Power in Mining: William Beedie Esson.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—The Hill Tribes of the Central Indian Hills: their Ethnology, Customs, and Sociology (with Lantern Illustrations): Wm. Crooke.

WEDNESDAY, NOVEMBER 23.

SOCIETY OF ARTS, at 8.—Long Distance Transmission of Electric Power: Prof. George Forbes, F.R.S.

GEOLOGICAL SOCIETY, at 8.—Note on a Conglomerate near Melmerby, Cumberland: J. E. Marr, F.R.S.—Geology of the Great Central Railway—Rugby to Catesby: Beeby Thompson.—On the Remains of *Amia* from Oligocene Strata in the Isle of Wight: E. T. Newton, F.R.S.

THURSDAY, NOVEMBER 24.

ROYAL SOCIETY, at 4.30.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Rotatory Converters: Prof. S. P. Thompson, F.R.S.

FRIDAY, NOVEMBER 25.

PHYSICAL SOCIETY, at 5.—On the Properties of Liquid Mixtures: R. A. Lehfeldt.—On certain Diffraction Fringes as applied to Micrometric Observations: L. N. G. Filon.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—La Cytologie Expérimentale: Dr. A. Labbé (Paris, Carré).—Publications of the British Fire Prevention Committee, Vol. 1 (1 Waterloo Place).—Allgemeine Biologie: Prof. M. Kassowitz, i. Band (Wien, Perles).—General Report on the Operations of the Survey of India Department during 1896-97 (Calcutta).—From Matter to Man: A. R. Dewar (Chapman).—Wild Animals in Captivity: A. D. Bartlett (Chapman).—Leçons de Chimie Physique: Prof. J. H. Van 't Hoff, translated by Prof. Corvisy, Part 1 (Paris, Hermann).—Traité Élémentaire de Mécanique Chimique: Prof. P. Duhem, Tome iii. (Paris, Hermann).—Through Arctic Lapland: C. Hyne (Black).—The Total Solar Eclipse, January 22, 1898 (Debra Dûn).—Traité d'Astronomie Stellaire: Prof. C. André, 1 Partie (Paris, Gauthier-Villars).—Practical Inorganic Chemistry for Advanced Students: C. Jones (Macmillan).—Birds of the British Isles: J. Duncan (Scott).—Aperçus de Taxinomie Générale: J. P. Durand (Paris, Alcan).—Life of Man on the High Alps; A. Mosso, translated by E. L. Kiesow (Unwin).

PAMPHLETS.—Review of Mineral Production in India for 1897 (Calcutta).—Replica di Krupp alla Protesta del Signor Bashforth: translated by F. Bashforth (Cambridge University Press).—Mines and Quarries: General Report and Statistics for 1897, Part 3, Output (Darling).—Temperature Entropy Chart; Captain Sankey (Rugby, Frost).—Sections and Thickness of the Lower Silurian Formations on West Canada Creek and in the Mohawk Valley: C. S. Prosser and E. R. Cumings (New York).—The Classification and Distribution of the Hamilton and Chemung Series of Central and Eastern New York: J. Hall and C. S. Prosser. Part 1 (New York).—Zwanzig Briefe g. z. Jöns Jakob Berzelius und Christian Friedrich Schönbein, 1836–1847, Herausgegeben von Prof. Kahlbaum (Basel, Schwabe).

SERIALS.—Morphologisches Jahrbuch, 26 Band, 2 Heft (Leipzig).—Scribner's Magazine, November (Low).—Observatory November (Taylor).—Encyklopaedie der Naturwissenschaften, Erste Abthg., 73 and 74 Liefg.; Dritte Abthg, 44 and 45 Liefg. EARLY MATHEMATICS.

Facsimile of the Rhind Mathematical Papyrus in the British Museum. With an Introduction by E. A. Wallis Budge, M.A., Litt.D., D.Lit., F.S.A., Keeper of the Egyptian and Assyrian Antiquities. 21 Plates. (Printed by Order of the Trustees.)

THE Rhind Mathematical Papyrus, a facsimile of which the Trustees of the British Museum have just issued, together with an introduction by Dr. Wallis Budge, is the document from which we gather most of what we know of the conception and use of mathematics by the ancient Egyptians. The papyrus does not contain a systematic treatise on mathematics, nor does it attempt to deal with the subject from a scientific standpoint. It consists rather of tables and sets of worked out problems, such as would constantly require to be solved by an Egyptian master-builder, land-owner, farmer or estate-agent. In consequence of the inundation, the area of an Egyptian farmer's holding was constantly changing in extent, so that the need of some practical method of measuring area was pressing. The farmer after harvest would need some plan for estimating the storage space required for his grain; the cattle-owner and employer of labour would constantly have to face problems connected with the distribution of fodder and provisions; the builder would require some method for estimating the angle of a pyramid to be erected upon a given base. Such problems as these were of every-day occurrence, and they forced the ancient Egyptian to employ his ingenuity in solving them. How far he was successful, and to what extent he proved himself a mathematician, we can gather from the Rhind Papyrus.

The papyrus consists of a roll, now broken in two pieces, which measure 10 feet 6 inches and 6 feet 9½ inches respectively. The text is written throughout in hieratic, but its actual date is not quite certain. Dr. Budge assigns it to a period not earlier than the beginning of the eighteenth dynasty, about 1700 B.C., but adds that the actual text goes back to an older period. It was probably a copy of a papyrus written in the Hyksos period, about 2000 B.C., by a scribe Ȧāh-mes, who states hat he himself copied an original work of the time of Ȧmen-em-hāt III., a king of the twelfth dynasty, about 2300 B.C.

Before treating of the contents of the papyrus it will be well to indicate briefly the limits in their knowledge of mathematics displayed by the ancient Egyptians, whose system was not so perfectly developed as that of the old Sumerian inhabitants of Babylonia. They approached their subject from the practical and not from the theoretical side; but in spite of numerous disadvantages in their system of notation, it must be admitted that they showed great ingenuity in dealing with the mathematical problems they attacked. With regard to integers the Egyptians used a decimal system of notation, but their system was inferior to the decimal system of the Arabs; for while in the Arabic notation each power of 10 is indicated by simply adding or removing a cipher, the Egyptians had a different name and symbol for each power; thus 1, 10, 100, 1000, 10,000, and 100,000 were each expressed by a different figure. This fact, however, did not prevent them from dealing without difficulty with very high numbers. In dealing with fractions, however, the case was different; here they experienced great difficulties, for, oddly enough, the Egyptian could only express divisions of unity. Any number, in fact, could be turned into a corresponding fraction by placing before it the word *re*, *e.g.* ½, ⅓, ¼, &c. By this system they could not express a fraction with a numerator greater than 1, though there was no limit to the divisor; in fact, in one of the sections on Plate *xf.* of this papyrus, the fraction 1/5432 occurs. There is one interesting exception, however, for they were able to express ⅔, but still as a division of unity, for they represented the fraction by a sign which may be rendered 1/1½. The Egyptians must have possessed multiplication tables, and those for the lower numbers were probably committed to memory; among these must have been included a table of 1/1½ values, for they could take ⅔ of a number by a single operation, and if they wished to take ⅓ of a number they halved its 1/1½ part. Besides adding and subtracting they were able, by means of their tables, without difficulty to halve and double, and to multiply and divide by ten and five. Multiplication by other numbers, however, they performed by repeated doubling and then adding; thus to multiply seven by six an Egyptian would double 7 = 14; he would then double the 14 = 28; and he would then add 14 to 28 = 42.

This brief sketch of the system of elementary Egyptian arithmetic will serve to explain the interesting arithmetical table which occupies the first six and a half plates of the Rhind Papyrus. This table was evidently worked out to help an Egyptian in his calculations with regard to fractions; it probably would not be committed to memory, but merely used for consultation like a modern table of logarithms. These six and a half plates contain the working out of a table expressing in simple fractions, with 1 for the numerator, the ratios of 2 to the odd numbers from 3 to 99, *i.e.* the fractions 2/3, 2/5, 2/7, &c. Plate i., for instance, gives the working out of these fractions from 2/3 to 2/15, from which we get the following table of results:—

2 divided by 3 = 1/1½
2 ,, ,, 5 = 1/3 + 1/15
2 ,, ,, 7 = 1/4 + 1/28
2 ,, ,, 9 = 1/6 + 1/18
2 ,, ,, 11 = 1/6 + 1/66
2 ,, ,, 13 = 1/8 + 1/52 + 1/104
2 ,, ,, 15 = 1/10 + 1/30

That this table was not due to the fancy of one scribe, but was a recognised table of values in general use, is proved by a fragment of papyrus found at Kahun in April 1889, on which part of the same table is written, and which shows the same values as the result of the division of two by the odd numbers from 3 to 21. The use of such a table is not at first sight very obvious, for if it is necessary to express 2/5 in fractions with 1 as the numerator, 1/5 + 1/5 is a simpler solution than 1/3 + 1/15. It has been suggested, however, that the Egyptians may have used the table for reducing fractions with higher numerators to fractions of unity; thus 5/11 might of course be expressed by the Egyptian as 1/11 + 1/11 + 1/11 + 1/11 + 1/11, but by means of the table a shorter

solution can be found, *i.e.* 5/11 = 1/11 + 2/11 + 2/11 = (by the table) 1/11 + 2/6 + 2/66 = (by their table of halves) 1/11 + 1/3 + 1/33.

On the right half of Plate xvi. is another somewhat similar but very much shorter table in a single column, giving some subdivisions of fractions which might prove useful in calculations, the results of course being expressed in divisions of unity, the table reading—

2/3 of 2/3 = 1/3 + 1/9
1/3 ,, 2/3 = 1/6 + 1/18
2/3 ,, 1/3 = 1/6 + 1/18
2/3 ,, 1/6 = 1/12 + 1/36
2/3 ,, 1/2 = 1/3

and so on. To the left of the table is a rule for finding 2/3 of a fraction, which reads as follows—

"To take 2/3 of a fraction. When it is said to thee, 'What is 2/3 of 1/5?' make thou its double and its six times. That is its 2/3. Thus is it to be done for every fraction that occurs."

The scribe evidently meant

$$2/3 \cdot 1/5 = 1/5 \times 2 + 1/5 \cdot 6 = 1/10 + 1/30$$

This general rule is exceedingly interesting, as it is the only one that occurs on the papyrus. In fact, the rest of the purely arithmetical part of the papyrus (Plates vii.–xii.) is thrown into the form of problems which are worked out with the object of being of practical use.

We have not space to do more than indicate the principal contents of the rest of the papyrus. Parts ii. and iii. (Plates xii.–xiv.) deal with the measurements of volume and area, in which given problems are worked out in estimating the amount of grain that can be stored in cylindrical and rectangular spaces of given proportions; in others the scribe has worked out the superficial area of fields of various shapes, the linear measurements of which are given; while diagrams are in some cases drawn of the shape of the fields. In this section of the work Dr. Budge remarks that the scribe has made a good many mistakes. Part iv. (Plate xv.) deals with the measurements of pyramids, of which six examples, with five figures, are given. The first on the page has the angle of the lower half of the southern stone pyramid at Dahshûr, four have the same angle as that of the second pyramid at Gîzeh, while the angle of the last is that of the pyramid at Mêdûm. Part v. (Plates xvi.–xx.) gives a worked out series of practical problems dealing with the reckoning of farm produce, the division of food among workmen, the cost of food for birds and animals, &c. They are all questions of practical interest, worked out, more or less, by rule of thumb. As Dr. Budge remarks in his Introduction to the Papyrus:—

"None of the examples or problems indicate that the Egyptians had any deep theoretical knowledge of arithmetic or geometry, but all of them show that they were very ready in making practical calculations."

Since the late Dr. Samuel Birch published an account of the contents of this document in the *Zeitschrift für Aegyptische Sprache* in 1868, the Rhind Papyrus has formed the subject of much discussion among both mathematicians and Egyptologists. A large body of students will, therefore, be grateful to the Trustees of the British Museum for placing in their hands the actual text of the papyrus in the form of a facsimile, which in beauty and accuracy of reproduction leaves nothing to be desired.

NEW ACCOUNT OF THE CHARACEÆ OF EUROPE.

Synopsis Characearum europearum. By Dr. Walter Migula. Pp. 176. Illustrated by woodcuts. (Leipzig, 1898.)

THIS is an abridgment of the author's large and elaborate work on the subject, which forms vol. v. of the new edition of "Rabenhorst's Kryptogamen-Flora von Deutschland, Oesterreich und der Schweiz." The latter is by far the most extensive and minute account of the European Characeæ which has yet appeared; but the present work, containing as it does almost all the illustrations, and most of the letter-press information in a condensed form, will, we think, be found the more useful for all ordinary purposes.

The first eighteen pages are taken up with an account of the structure of the Characeæ, with illustrations, and a chapter on collecting, examining, and preserving specimens. These are followed by a key to the genera and species. At the end there is a list of books and memoirs dealing with the Characeæ, also one of published sets of specimens.

The remainder of the book consists of a tolerably complete description of the genera and species, with figures of nearly all the latter. The arrangement followed is almost entirely that of Braun's "Fragmente"; but the anomalous species *Lychnothamnus stelliger* of Braun is elevated to a separate genus, *Tolypellopsis*, Migula (*Chara*, sect. *Tolypellopsis*, Leonh.), and *Chara rudis*, *C. horrida*, *C. crassicaulis*, and *C. delicatula*, which Braun regarded as sub-species, are treated as species. The author has gone to extreme lengths in the differentiation of varieties. For instance, *C. aspera* is credited with thirty-nine named forms, *C. fragilis* with thirty-seven, *C. crinita*, *C. ceratophylla*, *C. intermedia* and *C. contraria* have each more than twenty; while *C. fœtida* (excluding *C. crassicaulis*) has actually sixty-nine! The majority of these forms are of the author's own describing. From the larger book we learn that many of them are based on plants from single localities, and, judging by the citations, it is fair to suppose in some instances from individual specimens. Considering the extreme variation to which the vegetative parts of these plants are subject, it seems to us a great pity to multiply names by distinguishing every trivial form.

In the nomenclature of the species Dr. Migula has implicitly followed Braun, in several instances quite disregarding the accepted rules. It would, we think, have been as well to have mentioned some of the more generally known synonyms.

The book is, unfortunately, entirely in German. As it deals with the Characeæ of the whole of Europe, it would have been more widely appreciated had the key and the diagnoses of the genera and species, at least, been in Latin.

As we have remarked, the illustrations are the same as those in the larger work. They are on the whole decidedly good, especially those of the magnified portions of the plants, and several of the species are more completely figured than in any earlier book. Some of the representations of the entire plants are somewhat crude and inartistic, and that of *Nitella translucens* is very poor;

some, on the other hand, give a good idea of the habit of the plants.

Taking it altogether, the "Synopsis" is a very useful addition to the literature of the order, and it will be found a convenient handbook for reference.

H. and J. Groves.

OUR BOOK SHELF.

The Unconscious Mind. By A. T. Schofield, M.D., M.R.C.S. Pp. vii + 436. (London: Hodder and Stoughton, 1898.)

Dr. Schofield has set himself the task of familiarising the English public with the famous German theory of unconscious mental states. In his anxiety to let more accomplished psychologists speak for themselves he has, in many parts of his book, been content simply to reproduce the *ipsissima verba* of his authorities without criticism. Unfortunately he is himself scarcely psychologist enough to distinguish good authorities from bad, and trusts far too implicitly to the crudities and vagaries of such writers as Eduard von Hartmann. His work will hardly do much towards shaking the conviction of most English students of the science that "unconscious mind" is much such another phrase as "invisible colour" or "unextended body." Unconsciousness seems to mean very different things for him in the course of his argument. Instinct, he says, belongs to the "unconscious mind," because the animal executing the instinctive movement is unaware of its purpose. This seems quite unreasonable; the instinctive act is conscious enough in the sense of being attended both with sensation and with pleasure or pain; how then does the absence of knowledge of its biological value make it "unconscious"? Again we hear of "unconscious sensations," but they seem to mean no more than neural changes which would, under other conditions, be attended with consciousness. But surely it is obvious that it is one thing to say that if my attention had not been preoccupied a certain neural change would have resulted in a conscious sensation, and quite another to say that it has actually produced a sensation in my "unconscious mind." The unconscious execution of habitual mechanical processes is, of course, said to be presided over by "unconscious mind"; but where does the need of this undefined *tertium quid* come in? What is there, apart from the unscientific assumption as to the absolute heterogeneity of the psychical and physical, to prevent our saying quite simply that as a process becomes habitual and unconscious it ceases to be mental at all and becomes purely nervous? The believers in "unconscious mind" indeed profess to find it unthinkable that a combination of psychical elements should come to be replaced by a combination of physical elements, but they seem to have no better reason for their view than what Ebbinghaus well calls "this vulgar prejudice of the absolute distinction between mind and matter." It is probably not too much to say that Leibnitz's invention of the "petites perceptions" and Herbert's unlucky metaphor of the "threshold of consciousness" are responsible between them for an incalculable amount of psychological myth-making and confusion. Far the most valuable part of Dr. Schofield's book, the chapters in which he relates facts as to the therapeutic value of mental influences, is quite independent of his psychological theory.

A. E. Taylor.

Higher Arithmetic. By W. W. Beman and D. E. Smith. Pp. xvi + 193. (London: Ginn and Co., 1897.)

The book before us is for the service of teachers. It is not intended as a first course, but for those who have already had some experience, and wish to review and extend their knowledge.

The authors have adopted quite a new line of treatment, and instead of making the subject into a set of puzzles, as is so often done, they have introduced many improvements by showing how the subject is applied to every-day use. Thus we have a chapter on "Longitude and Time," and the reader is made acquainted with the relationship between them, together with the excellent system of universal time in use in the United States and nearly all over the world. Again, it is pointed out how a knowledge of arithmetic is applied to solve problems in elementary electricity. From the beginning to the end of the book the authors have made it their chief aim to point out the utility of the subject in its various applications. The book contains, besides an excellent list of definitions and etymologies arranged alphabetically, a great number of well chosen and appropriate examples.

The Story of Marco Polo. With Illustrations. Pp. xiv + 248. (London: John Murray, 1898.)

The preface is signed "Noah Brooks," and the little book is prepared specially for young readers. The plan is excellent, and well carried out. Selected extracts from Yule's "Book of Ser Marco Polo" are accompanied and woven together by a pleasantly written commentary, which seems to have been designed to interest the young people of the United States and the United Kingdom. Nothing could be better for the purpose. The extraordinary fidelity of many of Marco Polo's descriptions to fact is pointed out, and the incredulity with which they were received in a credulous age is duly dwelt on: a few of the more fanciful passages are also given, and the antiquity of these old stories noted. Probably many older people will see with surprise the minute exactness with which Marco Polo, six hundred years ago, described some of the most marvellous stock tricks of the modern Indian conjurers. The illustrations are not numerous, but very graceful and well selected. A map would have been a desirable addition.

H. R. M.

L'Art de Découvrir les sources et de les Capter. By E. S. Auscher. Pp. 278. (Paris: J. B. Baillière et Fils, 1899.)

Beginning with the physical properties of water, and dealing in order with the substances usually found dissolved in natural waters, the sources of these soluble materials, and the geological nature of the rocks through which subterranean waters percolate, the reader is introduced to the methods of water analysis in common use. The arrangement of strata and the characteristics of common rocks are explained with a view to making the circulation of underground waters easily understood. The third division of the volume, dealing with "La recherche des sources et des eaux souterraines," includes a chapter on "les signes extérieurs," which is only of doubtful scientific value, though many water-diviners doubtless receive great guidance from such considerations. Several of the illustrations are ingenious, and the book will be interesting to civil engineers who are concerned with questions of water supply.

Handbook of Insects Injurious to Orchard and Bush Fruits, with Means of Prevention and Remedy. By Eleanor A. Ormerod. Pp. x + 286; portrait and woodcuts. (London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd., 1898.)

Miss Ormerod has now added to her long and useful series of works on agricultural entomology by publishing a volume specially devoted to the insects and mites injurious to fruit. It is hardly necessary to say that the book is worked out in her usual careful manner, and freely illustrated. The principal fruits are arranged in alphabetical order, commencing with apple; and

under each, their insect enemies are enumerated. Fruit-growers who find their trees or bushes suffering from the attacks of insects, cannot do better than refer to this book to discover the cause and remedy. In a few touching lines, Miss Ormerod dedicates the book to the memory of her sister and co-worker, Miss Georgiana M. Ormerod, who was equally interested in entomological inquiries with herself. W. F. K.

Gas and Petroleum Engines. Translated and adapted from the French of Henry de Graffigny, and edited by A. G. Elliott, B.Sc. Pp. x + 140. (London: Whittaker and Co., 1898.)

A readable and instructive account of gas and petroleum engines is given in this little volume. The text can be easily followed by non-technical readers interested in gas and oil engines in use at the present time, and engineering students will find in the volume a good general survey of internal combustion motors. The subjects of the eight chapters are: the history of the gas engine, working principles of the gas engine, description of existing gas engines, carburetted air engine, petroleum engines, gas generating plant, engines for use with poor gases, and maintenance of gas and oil engines.

The Story of the Farm, and other Essays. By James Long. Pp. xv + 158. (London: *The Rural World* Publishing Company, 1898.)

The essays in this volume refer more to the economics than the science of agriculture. The author, who has had a long experience of agricultural public life, and has contributed many valuable manuals to the literature of farming, acknowledges that agriculturists fail to recognise the two great elementary requirements of the hour—technical instruction, to which alone farmers can look for their advancement in knowledge and success, and co-operation. The Countess of Warwick contributes an introduction to the volume, on "Women and the Future of Agriculture."

Publications of the British Fire Prevention Committee. Edited by Edwin O. Sachs. Vol. i. (London: British Fire Prevention Committee, 1898.)

Ten papers on methods of fire prevention and kindred subjects appear in this volume, which represents the first fruits of the establishment of the British Fire Prevention Committee. The papers call attention to the need for increased protection from fire by preventive measures, wider knowledge of methods of fire-combating, investigations of materials and forms of construction, and research into the causes of fires. They should thus be the means of imparting very useful knowledge, and obtaining active support for the movement for better preventive measures against fire, which led to the formation of the Committee under whose auspices this volume has been published.

The Story of the Cotton Plant. By F. Wilkinson, F.G.S. Pp. 199. (London: George Newnes, Ltd., 1898.)

This latest addition to the Library of Useful Stories, written by the director of the Textile School at Bolton, gives a clearly expressed and popular account of the chief cultivated species of the cotton plant, the pests and other injurious agents which molest them, and the methods of cultivation in different countries. The processes of picking, ginning and baling are described, and the plans for manipulating the cotton in carding, drawing, &c., dealt with. The early attempts at spinning are passed under review, and pave the way for an account of the modern spinning mule and the other processes in the spinning of cotton. The little volume, though perhaps not likely to be widely read, should be very popular in Lancashire.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Asymmetry and Vitalism.

Prof. Japp has so entirely changed his position that it is useless to attempt to follow him. I would desire, however, to correct misunderstandings into which he has fallen in respect of my contentions with reference to his original position.

I did not intend to suggest that life originated in a crystalline form; but merely that, as living things can now assimilate crystalline bodies, the first living organism may have originated in connection with and by utilising a crystal, and that the asymmetry of this original living organism may have been controlled by the accidental asymmetry of the original crystal.

Once life began, I presume it descended, as it does now, by section and so forth, and, as I cannot follow Prof. Japp's difficulties as to a particular asymmetrical system breeding the like, I cannot see how the intervention of intelligence is required for its propagation, any more than for the growth of a particular asymmetrical crystal, once it is started.

This preponderating influence of the parent entirely explains the other misunderstanding Prof. Japp has fallen into. I never suggested that the rotation of the sun, probably a very feeble cause, could make a seed, with its impressed asymmetry grow into a tree with a different asymmetry merely by bringing the seed from the northern to the southern hemisphere. All I suggested was, with reference to Prof. Japp's original position—namely, that at the *origin* of life the first living organism may have been given a particular asymmetry by its having been produced in one or other hemisphere. A cause which may have been quite sufficient to give this asymmetrical bias during the time of origination, may be quite inadequate to produce a change in the bias once it has been given.

Geo. Fras. FitzGerald.

Trinity College, Dublin, November 10.

Connection between Mânasarowar and Râkas-tâl.

Mr. Landor, in his account of his journey in Tibet, "In the Forbidden Land," claims to have disproved the connection between the lakes Râkas-tâl and Mânasarowar. The notice in Nature of November 3 speaks of the connection as being possibly open to doubt.

But it is not so. My brother, then Captain Henry Strachey, in the account of his visit to the lakes in 1846, published in the *Journal* of the Asiatic Society of Bengal, vol. xvii., gives full details on the subject. He crossed the stream that flows from Mânasarowar into Râkas-tâl at a point about a mile from the latter lake. He describes it as about a hundred feet wide and three feet deep, running rapidly from east to west in a well-defined channel. He did not visit the actual point at which this stream leaves Mânasarowar, but in 1849 I did so (see *R.G.S.J.*, vol. xxi.), and there is no more doubt about the fact than that the Thames runs past Richmond.

Mr. Landor, so far as his map and descriptions enable us to judge, and as the notice in Nature suggests, did not go far enough north between the lakes to admit of his ascertaining the facts bearing on the subject. Richard Strachey.

Lancaster Gate, November 12.

Arctic and Sub-Arctic Bees.

Of the wild bees of Alaska nothing is known, except that several species of humble-bees (*Bombus*) are common. Consequently, when Mr. Trevor Kincaid wrote me last year that he was going to Alaska, and would collect bees, I was expecting to see, on his return, quite a new bee-fauna. He collected carefully, and brought back a nice series, but all *Bombus!* No other genus was seen, although brightly-coloured flowers are quite numerous in Alaska. On the Pribilof Islands he found a fine new species of *Bombus*, which I named *B. Kincaidii*, but there was no other bee. I have written to Dr. W. H. Dall, to ask whether he ever saw any bees other than *Bombus* in Alaska. He replies that he collected there in 1868 four or five *Bombus*, and some wasps of the genera *Vespa* and *Pompilus*, but he has no record of other bees.

In Greenland, also, the bees are *Bombus*. Peary saw one quite at the northern end of that country. The one exception in America to the rule that only *Bombus* occupies the far north, so far as I remember, is the occurrence of *Osmia bucephala* at Great Slave Lake. In Europe and Siberia the same rule seems to hold, but doubtless several genera go further north than in America. *Andrena lapponica*, for example, is a decidedly northern type. The object of this note is to draw attention to the interesting question of the northern distribution of bees Those who have occasion to visit northern regions should collect what bees they can, noting the flowers they frequent, and in this way much valuable information may be gained. Probably some of your readers are already in a position to throw light upon the subject. T. D. A. COCKERELL.

Mesilla Park, New Mexico, U.S.A., Nov. 6.

Why Birds are not Killed by Eating Poisonous Fruit.

THERE is a great difference of opinion on this subject. While some maintain that birds do not eat fruits of this kind, others hold that they eat only the surrounding pulp, as of the berries of Taxus, which is perfectly harmless, whereas the seed is very poisonous; others, again, have maintained that they do not eat sufficient to be poisonous. The real fact is, I believe, that none of these statements are true, but that actually the birds eat largely of these berries, both pulp and seed, and that they very shortly afterwards eject the seeds and skins by the mouth, thus avoiding any poisonous action.

The first experience I had of this habit was in finding in September last an immense number of thrushes and missel-thrushes feeding on the berries of *Pyrus aucuparia* in Sutton Coldfield Park. At least a square mile of ground had every patch of grass covered with the ejected seeds and skins of these berries, all the pulp having disappeared, while the colour of the skins was as bright and fresh as when they were swallowed; showing that they could not have passed through the alimentary canal. Each of the pellets was flat and round, and about the size of a sixpence. The birds were incessantly flying to and fro betwixt the trees in the adjoining woods and the park. The excessive drought of last summer, by decreasing the supply of their ordinary food, was evidently the cause of their attacking the berries at this early period.

The next evidence I had of this being the explanation of their immunity from the effect of poisonous food was in October last, when I found on Boxhill, in company with Prof. Conwentz, of Dantzic, a number of similar pellets, but consisting entirely of the seeds and skins of yew berries; the former being as bright green, and the latter as scarlet as they were on the tree. In each of these pellets I counted twenty or more seeds.

The real difficulty in accepting this explanation is that, so far as I know, no one has actually seen the birds eject the seeds. Two friends of mine saw, the other day, what was very nearly the accomplishment of the process. A thrush was seated under a well fruited yew, and going through violent spasmodic contortions, the wings drooping on the ground; they thought it was ill, but it flew away strongly as if there was nothing the matter.

The idea that these birds only suck off the pulp from the berries is, I think, fallacious. Prof. Conwentz and I found under a large tree on Boxhill a great number of small fruit-bearing shoots, which had clearly been bitten off by squirrels; the ground was quite covered with seeds divested of their aril, and unbitten, though a few berries with the pulp bitten had been dropped by the squirrels. Mr. Morton Middleton tells me that at Dicksgrove, Co. Kerry, the yew-berries are largely eaten by thrushes, missel-thrushes, blackbirds, greenfinches, linnets, &c., and afterwards rejected, but he has not seen the birds in the act of doing this. He says, however, that turkeys, not being able to eject the seeds, are killed by them, although Rhind ("Vegetable Kingdom") says that these, as well as peacocks and fowls, eat them with impunity. Mr. Bennett (NATURE, October 13, 1898) asks for information as to the effect of birds and animals eating poisonous plants, and says that blackbirds eat the berries of *Atropa belladonna*. It does not appear that this was more than a supposition, neither is there any observation, so far as I am aware, as to what part of the berry, seeds or pulp, is poisonous. He says that mice eat the seeds of *Datura stramonium*. Here again we do not know whether they eat more than the kernel, which they would readily extract from the seed, as I have found them do in the case of *Ranunculus repens*, a small hole being bitten at the edge of the seed, while every kernel was extracted from the double-handfuls of seeds, which were collected in heaps.

"J. C." (NATURE, vol. lviii. p. 597, October 20, 1898) saw thrushes feeding freely on the berries of *Daphne mezereon*, an undoubtedly poisonous plant. In this instance there can be little question that they eject the seeds. He says they were so stupefied that they might apparently have been taken with the hand.

Mr. E. Langley, in the same number of NATURE, says that he saw blackbirds also eat these berries, but they did not appear the worse for a number of them.

Gilbert White ("History of Selborne, 1789, 329) speaks of milch-sows being killed by yew-berries, while "barrow-hogs and young sows" did not suffer. He attributes this result to the former being weak and hungry, and therefore eating a much larger quantity.

Prof. Tuson found (*Field*, 1877) that pheasants were killed by the leaves of yew, and there are several similar instances recorded since that date.

A. von Kerner made a number of experiments to show that seeds eaten by blackbirds, germinated in the following June; whilst those not so eaten, remained on the ground three or four years. O. Kirchner says that a species of Motacilla eats the berries; but this I regard as a doubtful statement. I have frequently seen them capture flies attracted by the fruit, but have never seen them touch the fruit itself. Every one is, of course, familar with the manner in which owls disgorge the fur and bones of mice and skulls of small birds, a habit which Mr. Harting tells me is shared by all the raptorial birds, as well as by shrikes, flycatchers, and rooks; and there are other facts alluded to by Sir Herbert Maxwell in his "Memories of the Months," and others of insects feeding on deadly poisons without any injury. The habit of ejecting the indigestible parts of their food by birds, seems to require further observation and experiment. JOHN LOWE.

Sun-spots and Air Temperature.

THE following comparison is, I think, instructive:—

Make out a table (from Greenwich data), in which each month since the beginning of 1841 is simply characterised as + or −, according as its mean temperature has been above the average (warm), or below it (cold).

Then, in each five-year group having a sun-spot maximum year central, count the warm and the cold months; and the same with five-year groups having a minimum central. We get these tables:—

Max. groups.	*a* Warm months.	*b* Cold months.	*a* − *b*
1846–50	38	22	+ 16
1858–62	32	28	+ 4
1868–72	34	26	+ 8
1882–86	33	27	+ 6
1892–96	35	25	+ 10
	172	128	+ 44

Min. groups.	*a* Warm months.	*b* Cold months.	*a* − *b*
1841–45	26	34	− 8
1854–58	30	30	0
1865–69	35	25	+ 10
1877–81	26	34	− 8
1888–92	17	43	− 26
	134	166	− 32

Thus, in each of the maximum groups, there is an excess of warm months; and taking the whole, an excess of 44 warm months. In most of the minimum groups, on the other hand, an excess of cold months; total excess, 32 months.

With regard to the exceptional case—1865–69—in the second table, it may be worth remarking that 1860–70 is one of Brückner's warm periods. It seems to me that a consideration of both those cycles—the sun-spot cycle of about 11 years, and Brückner's of about 35 years—furnishes the clue to a great deal of our weather. A. B. M.

On Keeping Marine Organisms Alive in Small Aquaria.

IN NATURE of November 10 (p. 44), a contrivance is mentioned by the use of which the sea-water in a small aquarium can be kept in motion. The same kind of apparatus has been employed during the winter 1897-98 in Kiel, for keeping Peridinea and Diatoms of the Plankton in a healthy condition. Prof. Geo. Karsten has described the apparatus used in the *Wissenschaft. Meeresuntersuch. der Kommiss. z. wissenschaft. Untersuch. d. deutsch. Meere in Kiel und der Biolog. Anstalt a. Helgoland*, vol. iii. part 2, March 1898, p. 8. In this case a clinostat-clockwork was used, and the plunger rose five times in three minutes. The bell-jar, serving as an aquarium, was very small, holding about 1·5 litre. Ceratium and Skeletonema got on very well, the same plants dying off rapidly on being kept in water at rest.

OTTO V. DARBISHIRE.

Owens College, Manchester.

THE NOVEMBER LEONIDS OF 1898.

VERY unfavourable weather was experienced all over the country at the middle of November, and the return of the Leonid meteors was very scantily observed. At many stations no observations whatever were possible between November 13 and 16, while at other places only one of these nights was partially clear. As a result of the bad atmospheric conditions, very few meteors have been recorded. But it seems certain, from a comparison of the fragmentary observations obtained at various places, that, apart from the unfavourable influence of the weather, the meteoric shower did not nearly answer expectation. In fact, the number of meteors visible appears to have scarcely exceeded the average number that may be counted on an ordinary mid-November night. It is true that the observations did not cover the whole of the three nights of November 14, 15 and 16, and were, moreover, effected in most cases under circumstances little calculated to ensure successful results. But making every allowance for the difficulties encountered, the feeble character of the shower is still significant, and proves that the earth in recently crossing the node of Tempel's comet of 1866, did not encounter the denser part of the meteoric stream, but a very attenuated region far in advance of the associated comet. Indeed, the recent display appears to have been scarcely richer than those of 1879 and 1888, when the comet was not a great distance from its aphelion. Of course, the real shower may have occurred in the daytime, but it would scarcely escape recognition in America or some other distant part, for observers all over the world are keenly alive to the attractions and the importance of the Leonid display, and have been on the alert to witness it.

Descriptions of the recent shower from the United States are not dissimilar to those from our own country. Of course, we cannot rely upon the exaggerated statements published in some of the American newspapers, or sent home by the New York correspondents of certain English journals. One of the latter, writing on November 15, says: "Astronomers throughout the United States watched the shower of Leonid meteors, which appeared between midnight and five o'clock this morning. Many of the meteors made brilliant flashes across the sky, and left fiery trains. One meteor in Orion lit up the entire city of New York at about one o'clock in the morning, and fell hissing, the sound indicating its close proximity." More trustworthy accounts from astronomical observers at the Lick Observatory, Mount Hamilton, the Princeton Observatory, and others at Richmond, Virginia, agree that the late display was a disappointing one, the meteors seen being neither numerous nor brilliant.

With regard to observations made in this country, the writer has received reports from London, Oxford, Bridport, Yeovil, Cardiff, Chester, Loughton (Essex), Cirencester, Stone (Staffs.), Leeds, Southport, Belfast, Dumfries, and several other places. A few quotations from these may perhaps be interesting:—

Belfast.—A watch was maintained on November 12 to 15h. 30m., but no Leonids observed. On the following night (13th), to the same time, six meteors were recorded, and of these three may have been Leonids. On November 14, the sky was overcast to 16h. 40m.; then it partly cleared; but there was a good deal of mist, and the stars shone very dimly. Between 16h. 40m. and 17h. 15m. the observer saw ten fine Leonids; but the sky became cloudy again, and observations were discontinued. The shower was regarded as a fairly strong one under the conditions, and the maximum appeared to be at about 17h.—W. H. Milligan.

Southport.—Observations were made at the Meteorological Observatory on November 14, 13h. 30m. to 17h. 30m., and the following were the hourly number of meteors (nearly all Leonids) noticed by one observer:—

h. m.		h. m.		
13 30	to	14 30	=	15 meteors.
14 30	to	15 30	=	10 ,,
15 30	to	16 30	=	3 ,,
16 30	to	17 30	=	2 ,,

The meteors were small, not one being brighter than a 1st mag. star. The scarcity of meteors, only five being seen between 15h. 30m. and 17h. 30m., is remarkable.—J. Baxendale.

Yeovil.—On November 14 the sky was clear, but only two or three meteors were remarked in the two hours between 13h. and 15h.—Rev. T. E. R. Phillips.

Cirencester.—Weather clear during the whole night of November 14, and only a little fog at low altitudes. Observations were made from a window facing E., between 11h. 45m. and 12h. 50m., but no meteors were seen. The sky seemed unaccountably light.—Miss E. Brown.

Gateshead. On November 13, between 10h. and 15h., the atmosphere was favourable, and observations were made at short intervals, but no meteors were seen.—Dr. A. W. Blacklock (*English Mechanic*).

Northants.—On November 14, from midnight to 15h., a watch was kept with results almost *nil.* The sky was, however, partially veiled with clouds through which only a few stars could be seen. There was a very brilliant meteoric flash at 13h. 55m.—F. H. Wright (*English Mechanic*).

Bristol.—On November 12 the clouds passed off at 15h., and the sky was watched intermittently until 17h. Only seven meteors were seen. There was no sign of radiation from Leo. At 16h. 4m. the sky was illuminated, probably by the outburst of a large meteor in a region of the heavens hidden to the observer. The nights of November 13 to 19 were all overcast, and no observations could be obtained.—W. F. D.

Chester.—On November 16, between 10h. and 13h., six plates were exposed for 30m. each, but no meteor trails were secured. The meteors appeared to be scarcer than on any ordinary night. At 12h. 8m. a Leonid of the apparent brightness of Mars was seen, and with the exception of a small, swift Perseid nothing else was recorded.—F. W. Longbottom.

The remainder of the reports are stories of failure in consequence of the weather. At many places a series of dense fogs occurred just at the important time. In spite of these drawbacks, however, the fact remains that at certain stations on November 15 a clear sky invited observation, but presented very few meteors. It is true that Mr. Milligan saw some brilliant ones in the hazy sky of November 14, 16h. 30m. to 17h. 15m., and that the observed maximum of the "shower" seems to have occurred at nearly the same time as last year. But the phenomenon, so far as it was observed, was quite of minor character, and observers who saw nothing what-

ever, owing to the weather, may take comfort in the reflection that they lost very little. Of course, further observations may come to hand from distant places where the stars shone and meteors fell. If so, we may possibly have to modify our present ideas; but from the materials now before us, we can only draw the following conclusions:—

(1) The state of the atmosphere generally was very unfavourable for the observation of meteors.

(2) The number of meteors which appeared was small, and never at any time formed a display of special richness.

(3) The earth was too far in advance of the cometary nucleus to encounter the denser region of the meteoric stream.

But the observations obtained this year, if of a negative character, and very discouraging from an observational point of view, will yet be important as affording evidence of the tenuity of that section forming the vanguard of the stream.

The meteoric observer, disappointed as he has been in 1897 and 1898, may yet look forward with every confidence to the brilliant displays which will mark the years 1899, 1900 and 1901. W. F. DENNING.

NOTES.

IT has already been announced that in connection with the Royal Society the Colonial Office has instituted a Commission to investigate the subject of tropical malaria. We are now informed that the medical officers selected for the work in Africa are Dr. D. Daniels, of the Colonial Office Medical Service, Dr. Stevens, and Dr. Christopher. Dr. Daniels has sailed for India in order to make himself acquainted with the recent observations of Surgeon-Major Ronald Ross, of the Indian Medical Service, connecting the spread of malarial disease with certain species of mosquitoes. The two other gentlemen referred to will go direct to Nyasaland, in British Central Africa, to study malarial disease in that locality; and will eventually be joined by Dr. Daniels. With the knowledge acquired in a comparatively temperate climate, where, however, fever has of late years been peculiarly fatal, the three medical officers will, at a later date, visit West Africa, possibly on the Niger. The Royal Society proposes to contribute towards the expense of the investigation, the British Government, through the Foreign and Colonial Offices, finding the remainder. It is estimated that the investigations will occupy about two years, and reports will be submitted from time to time to a Committee nominated jointly by the Royal Society and the Secretary of State.

IT will be remembered that the late Mr. Alfred Nobel left almost the whole of his fortune to be converted into an international fund for the advancement of scientific research (see NATURE, vol. lv. p. 232). The bequest gave rise to a dispute, which we are glad to learn has been settled by a compromise between the contesting parties. The relatives of the deceased will receive 3,800,000 Swedish kronor, or about 211,000*l*., so that there still remains for the prizes the sum of 25,000,000 kronor, or nearly 1,400,000*l*. The income, computed at the rate of 3 per cent., will make the five prizes worth 150,000 kronor, or 8300*l*. each. It is expected that the compound interest during the time, which will necessarily be long, that will elapse before the prizes can be awarded, will increase the capital so as to cover the cost of managing the funds and the work entailed in properly distributing the prizes. It will be remembered that these prizes are to be awarded annually to persons making the most important discoveries in physics, chemistry, physiology or medicine. There is also to be a prize for the best literary contribution upon the subject of physiology or medicine, and also one for any person who has achieved the most or done the best things looking towards the promotion of the cause of peace throughout the world.

M. A. MICHEL LÉVY has been elected a corresponding member of the Berlin Academy of Sciences.

WE regret to see the announcement of the death of Dr. James I. Peck, assistant professor of biology in Williams College, and assistant director of the Marine Biological Laboratory at Woods Holl.

THE first competition offered by the Nansen Fund, which was established soon after the return of the *Fram* in 1896, has just been advertised. The subject is a thorough work in embryology based on original investigation, and the amount of the prize is 1500 kroner (about 80*l*.) The result will be announced at the annual meeting of the Christiania Academy of Science, May 3, 1900.

THE Christmas Course of Lectures, specially adapted to young people, at the Royal Institution, will be delivered this year by Sir Robert Stawell Ball, F.R.S. The subject will be "Astronomy," and the lectures (which will be illustrated by models and the optical lantern) will deal with the sun, the moon, the inner planets, the great planets, shooting-stars, and new methods. The first lecture will be delivered on Tuesday, December 27, at three o'clock, and the remaining lectures on December 29 and 31, and on January 3, 5 and 7, 1899.

THE death is announced at Paris, at the age of seventy-four, of M. J. N. Raffard, distinguished for his inventions and papers on science and technology. His inventions include governors for engines, several ingenious dynamometers, and many other appliances; he was the first to construct in Paris an electric tram-car worked by accumulators. He was a member of the Committee of Mechanical Arts of the Paris Société d'Encouragement, and also of the Editorial Committee of the *Revue de Mécanique*.

SIR GEORGE BADEN-POWELL, K.C.M.G., whose death, at the comparatively early age of fifty-one, we regretfully announce, took an active interest in scientific affairs, and in many ways assisted the advancement of natural knowledge. He was the son of the Rev. Prof. Baden-Powell, the Oxford geometrician and geologist. In 1896, he rendered a most valuable service to astronomy by conveying a small party of observers to Novaya Zemlya to make observations of the total eclipse of the sun. It will be remembered that on account of unfavourable weather the eclipse was not observed in Norway, where most of the British observers were situated; but, fortunately, better conditions prevailed at Novaya Zemlya, and excellent photographs were obtained of eclipse phenomena. The total failure of the British expeditions was thus saved by Sir George Baden-Powell's timely aid. His death will be mourned by many friends in the scientific world.

SIR JOHN FOWLER, K.C.M.G., Bart., the distinguished engineer, died on Sunday, at the age of eighty-one. His name is associated with some of the greatest engineering triumphs of this century. He was responsible for the design and construction of the Underground (Metropolitan) Railway, and carried out the scheme successfully in the face of gigantic difficulties and great opposition. He was engineer-in-chief of the Forth Bridge, which he designed in association with Sir Benjamin Baker, and he planned and commenced in 1875 the Sudan Railway to Khartum, now on the point of completion. It was in consideration of his work for the benefit of Egypt that in 1885 the Queen conferred upon him a Knight Commandership of St. Michael and St. George. For his services in connection with the Forth

Bridge, he was created a Baronet in 1890. He was president of the Institution of Civil Engineers in 1866, and delivered from the chair a very memorable address on the requirements of a complete engineering education. In 1890 he received the honorary degree of LL.D. from Edinburgh University.

PROF. CHARLES-MICHEL BRISSE, whose death occurred on October 13, was born in Paris on September 8, 1843, and lived a life of activity and usefulness. He was professor of mathematics at the lycée Condorcet for twenty-four years, and he also held the posts of tutor at the École Polytechnique, supplementary professor at the Conservatoire des Arts et Métiers, professor at the École Centrale, and professor at the École des Beaux-Arts. He was the author of papers on the displacement of figures and on the general theory of surfaces, and he translated into French several English and German works on the higher branches of mathematics. He also published numerous memoirs on actuarial subjects. In collaboration with M. Andre and M. Rivière, he published two editions of a "Course de Physique" for use in classes of mathematical physics. He was connected with the *Journal de Physique* for many years, and an appreciative note upon his services to the journal and to science appears in the November number.

THE temperature-entropy or "theta-phi" diagram of a substance, in thermodynamics, has been made well known to engineers through the writings of Mr. J. Macfarlane Gray. Those who wish to become familiar with an actual theta-phi diagram, or to study the properties of steam by its aid, will be glad to know that a diagram for one pound of steam at temperatures from 100° to 400°, designed by Captain Sankey, is now published by Messrs. Albert Frost and Sons, of Warwick House, Rugby. The basis of the chart is the water line and saturated steam line, and the space between these is closely divided by constant pressure and constant volume lines, which are extended into the superheated steam field; lines of constant dryness-fraction are also given. There are scales giving total heat, water-heat, and internal energy, from which these quantities can be read off without interpolation.

MR. PHILIP E. BERTRAND JOURDAIN sends us several notes reprinted from the *Journal* of the Royal Microscopical Society, 1898, pp. 395–400, dealing with improvements in microscopic lenses, with especial reference to photo micrography. In the first of these notes he describes and figures an apochromatic objective and projection-ocular without fluorite, computed by Prof. Charles S. Hastings; but no information as to the precise nature of the glasses seems to be divulged by the makers. In a second note Mr. Jourdain describes a method of adjusting the sizes of the coloured images yielded by the Cooke lens; while a third note is devoted to a description of the planar lens recently computed by Dr. Rudolph, which, on account of its large aperture and wonderfully perfect astigmatic corrections, is admirably adapted for low-power micrography.

A SHORT article on the colours of lakes and seas, by Prof. Richard Abegg, of Göttingen, has been reprinted from the *Naturwissenschaftliche Rundschau*, xiii. 14. The author upholds the theory of Bunsen to account for the connection between the blueness of water and its purity: namely, that water itself absorbs red and yellow rays in preference to blue, and the purer the water the greater distance has the light to travel before being reflected by suspended particles, and therefore the greater the preponderance of blue. Bunsen's theory of selective absorption, combined with Soret's application of Tyndall's theory of the colours of the sky to water, are regarded by Prof. Abegg as affording a satisfactory qualitative solution of the question; but a number of interesting problems of a quantitative character still remain to be solved, and in this connection M. Spring's investigations are criticised at some length.

Some remarkable facts with regard to the electrical transmission of power in mining were brought forward by Mr. W. B. Esson in a paper read at the Institution of Civil Engineers on November 15. It was shown that the disadvantages attendant upon expensive transport of ore have been to a large extent neutralised by the electrical transmission of power. By using electrically-transmitted power the crushing-mills can be placed at the mine, and the serious expense of transporting the ore to the site of the water-power can thus be saved. Generally, electricity furnishes the only practicable means for transmitting power for mining operations, and the ease with which a copper wire can be carried over any kind of country, together with the plastic nature of the material, renders the electrical conductor the simplest and most trustworthy of all vehicles for power transmission. The plant erected at the Sheba Gold Mining Company's mine for the electrical transmission of power to the crushing-mills, five miles distant, was described by Mr. Esson, and the cost of milling was shown to be 1*s.* 8*d.* per ton of ore, as against 6*s.* 1*d.* per ton when aerial ropeway transport was used, and 1*l.* 12*s.* 6*d.* per ton during the time of ox-waggon transport. The water-power is obtained by a dam across the Queen's River, two miles above the generating station, to which the water is conveyed partly in open race and partly in tunnel. The maximum head derived is 32 feet. The turbines are of the Victor horizontal type, driving a countershaft of 300 revolutions per minute by ropes, and are together capable of developing 396 horse-power. The generating plant consists of three alternating-current dynamos supplying current at 3300 volts. The current is transmitted by cables to the mine, and at the receiving-house the pressure is reduced to 100 volts for driving motors and lighting the workings. The crushing-mill at Sheba works night and day; and in one year, of the possible 365 days of 24 hours each, the pressure cut off the conductors was only 4 days, 8 hours, 22 minutes, which were chiefly occupied in inspecting the water-race, overhauling the belts, ropes, &c., and in executing general repairs to the machinery. The efficiency of the plant from the turbine shafts at the generating station to the motor shafts at the mine may be taken as 70 per cent.

"IT is now some eighteen years since Mr. George Eastman, as an amateur photographer, began experimenting in a dark room in his own house with the intention of manufacturing photographic dry plates. . . . This was the modest beginning which blossomed in 1881 into the Eastman Dry Plate Company." So writes "Hermes" (*Commerce*, October 26, p. 785) in his interesting article under the heading "Every one his own photographer." Most of our readers have practised the art of photography at some time or other, and many have, without doubt, been users of the well-known Kodak and Eastman's films and papers. It is with these that the writer of the above-mentioned article deals; in fact, he gives an interesting digest of the history of this big firm since its commencement. So great and rapid has been the growth of this company, that in addition to their large manufactories in Rochester, New York, an equally large establishment has grown up in England, having its chief works at London and Harrow. The latter send their photographic materials over the whole world, with the exception of America, which is supplied from Rochester. Users of these materials will therefore read this article with interest, for not only will they be made acquainted with the numerous buildings and show-rooms by means of excellent reproductions, but the workshops and other manipulating sections are interestingly described by "Hermes," who has made a tour of all the company's premises.

THE *Engineering and Mining Journal* announces that Dr. Napier Ford has invented a substitute for rubber, namely perchoid, which is described as an oil that has undergone a high degree of oxidation. The oil is heated with litharge, stirred long and continuously, and then allowed to cool. Specially prepared tow is then dipped into it and placed in wire baskets, and exposed to air. The oil admitted to the filaments of the tow thus becomes wholly oxidised. This is drawn through rollers, and comes out a leathery material closely allied to, if not identical with, rubber. Its tenacity is increased by mixing sulphur with it. It is said that perchoid can be rolled as thin as a piece of tissue-paper, and that it makes leather impervious to moisture, though not to air.

SOME ten years ago a French missionary started the systematic rearing of two kinds of spiders for their web, and the *Board of Trade Journal* states that a spider web factory is now in successful operation at Chalais-Meudon, near Paris, where ropes are made of spider web intended for balloons for the French military aeronautic section. The spiders are arranged in groups of twelve above a reel, upon which the threads are wound. It is by no means easy work for the spiders, for they are not released until they have furnished from 30 to 40 yards of thread each. The web is washed, and thus freed of the outer reddish and sticky cover. Eight of the washed threads are then taken together, and of this, rather strong yarn cords are woven, which are stronger and much lighter than cords of silk of the same thickness. These spider web ropes are very much more expensive than silk ones, but it is hoped to reduce their cost somewhat in the future.

AT the meeting of the Academy of Science of St. Louis on November 7, Mr. James A. Seddon, of the Missouri River Commission, presented a paper on resistance to flow in hydraulics, in which the point was made that relatively a small part of this resistance, so far as open streams were concerned, was directly attributable to friction against the bottom and limiting banks, but that the resistance was found acting between accelerations and impacts, and showed in forced distortions of the free surface, from which forms the energy passed into internal motion.

WE learn from *Science* that the State Legislature of Vermont has passed an Act providing for the equipment and maintenance of a State laboratory, which shall include in its work "the chemical and bacteriological examination of water-supplies, milk and all food-products, and the examination of cases, and suspected cases, of diphtheria, typhoid fever, tuberculosis, malaria, and other infectious and contagious diseases." The sum of 1000*l.* has been granted for the establishment of the laboratory, and 1600*l.* per year voted for current expenses. Dr. J. H. Linsley is director of the laboratory. It appears that only three States have established similar laboratories—Michigan, Massachusetts and New York.

WE have received from Prof. B. Sresnevsky, director of the Iouriev (Dorpat) Observatory, the twelfth yearly report upon the rainfall of the Baltic provinces of Esthonia and Livonia. The observations refer to the year 1897, and contain monthly and yearly values, and the number of rainy days, for 125 stations, and the same values are also grouped into districts. Although not stated in the title, the work also contains temperature observations made at 8 a.m., and these are treated in the same way as the rainfall values. The ten-yearly mean of rainfall for the whole district is 21·9 inches, and the average number of rainy days is 162. The driest month is January, and the wettest, July. The general mean of the yearly temperature (for 8 a.m.) is 39°·4 (January 18°·5, July 62°·2). The results have been prepared by Dr. A. von Oettingen, formerly director of the Dorpat Observatory, and we are glad to see that, as soon as values for fifteen years have been obtained, it is proposed to issue a general summary, with diagrams.

THE Pilot Chart of the North Atlantic Ocean, published by the Hydrographer of the U.S. Navy for November, gives some interesting details of the track followed by the recent destructive hurricane in the West Indies. The centre of the storm passed to the southward of Barbados at 9h. 30m. p.m. on September 10; and reached Kingstown, St. Vincent, at noon on the 11th. From St. Vincent, the hurricane moved north-westward at the low rate of six miles per hour, and gales were experienced within a radius of 75 miles from its centre. On the 12th and 13th it was central to the west of the Lesser Antilles, turning to the northward on the latter date. On the 14th it continued its north-westerly course, recurving to the north-east on the 17th, near latitude 30° N. and longitude 71° W. The British steamship *Irrawaddy*, from port of Spain to New York, encountered the hurricane on the 11th, and kept within the storm area until the 18th; she had strong winds to gales of hurricane force throughout this period. On the 18th and 19th the storm pursued a north-easterly course, moving at the rate of twenty-five to thirty miles an hour, its area being increased considerably. The last report received by the U.S. Office was from the British steamship *Hesperia*. She reports, latitude 42° N., longitude 42° W., on September 20: "Winds S.S.W., force 10, shifting N.W., lowest barometer 29·62 inches; squalls blowing with terrific force; sea at times mountainous." The storm seems to have followed a somewhat more northerly and seaward course than the average track for September, as calculated by Padre Viñes in his investigation of the general movements of West Indian hurricanes, published by the Weather Bureau of Washington.

THE next volume of the *Transactions* of the Woolhope Field Club will contain a valuable paper (of which some copies have been printed) on the Hereford earthquake of December 17, 1896. The paper is the joint work of Mr. H. Cecil Moore, the Secretary of the Club, Mr. R. Clarke and Mr. A. Watkins, and gives the results of careful inquiries made in the central county of Herefordshire with regard to the damage caused by the earthquake. In the city of Hereford alone, it appears that 218 chimneys had to be rebuilt; but in the parish of Fownhope the damage was relatively greater, for twenty-two chimneys were repaired or rebuilt. The authors remark that a circle of six miles radius, with its centre at the centre of the ancient upheaval of the Woolhope Valley, includes by far the greatest damage in the conuty. The paper is illustrated by two plates, one showing the fractures in several pinnacles of Hereford Cathedral and other churches; the second being a map of the county, on which are marked the places where buildings were damaged.

THE Geological Survey of England and Wales has lately published short explanations of the new series maps relating to the country around Bognor and Bournemouth, by Mr. Clement Reid. We are now able to call attention to another explanation relating to Eastbourne, by the same author, and printed for H.M. Stationery Office, price 6*d.* It contains a general account of the geology of this favourite residential district, which includes not only Eastbourne, but also Newhaven and Seaford. The strata comprise the Cretaceous rocks from the Weald Clay to the Upper Chalk, the Lower Eocene strata, and superficial Drifts. Illustrations are given of the characteristic fossils. Mr. Reid calls attention to certain disturbances seen on the foreshore near Beachy Head, and a study of these leads him to conclude that the Chalk of the South Downs, unlike that of the North Downs, is not connected across the Channel with France.

Brief notes on water supply and economics are also given in this little pamphlet.

AMONG noteworthy acquisitions by purchase referred to in the Report of the Trustees of the Australian Museum, which has just come to hand, is the Mount Stirling meteorite, a mass of meteoritic iron weighing more than 200 lbs., found in Western Australia; a valuable collection of opalised reptilian remains, including the remains of the Mesozoic reptile *Cimolisaurus leucoscopelus*; a specimen of the very rare Golden-winged Parakeet (*Psephotus chrysopterygius*) from Port Darwin, only three examples of which are believed to be known; and some eggs of the Jabiru (*Xenorhynchus asiaticus*). The total number of acquisitions was 11,099, of which 7379 were presentations, 1455 were exchanges, 277 were purchases, and 1888 were collected by members of the staff. Sir William MacGregor contributed nearly one thousand ethnological specimens from his New Guinea Collection. The curator, Mr. R. Etheridge, jun., points out that the museum staff needs a trained collector. At present the funds at the disposal of the Trustees will not permit of such an appointment being made, which is regretted because museums and institutions in other countries send collectors to Australia and take away the best specimens.

FOREST resources are receiving increased attention in many places. A short time ago we recorded the establishment of the New York State College of Forestry for the professional education of the managers of the forests of the State. A report on the forestry conditions of Northern Wisconsin, containing the results of an investigation carried out by Mr. Fillibert Roth, has now been published by the Wisconsin Geological and Natural History Survey. As in many other cases, the forests of the State are shown to have been treated destructively. The wooded area is steadily being reduced, and at present nothing is done to protect or re-stock the "cut-over" lands, which are now unproductive waste land. Mr. Roth estimates that this policy causes a loss of 800 million cubic feet of wood per year to the State, besides driving from the State the industries which have been most conspicuous in its development, depriving a cold country of a valuable factor in its climatic conditions, and affecting detrimentally the character of the main drainage channels of the State. It is hoped that the report will aid in the formulation of rational forestry legislation, and so help to develop and restore the great forest resources of the State of Wisconsin.

MANY items of interest are contained in Mr. Edgar Thurston's report on the Madras Government Museum for the year 1897-98. How much appreciated the museum is may be judged by the fact that as many as 47,260 visitors have been admitted on a single day. The proportion of those able to sign their names to that of those unable to do so was about 1 : 6 on week days and 1 : 3 on Sundays. This is satisfactory as showing that Sunday opening continues to appeal to the educated classes, who are prevented by business from visiting the museum on week-days. Dr. A. G. Bourne made three tours during the year, viz. to the South Arcot district, the Palni, and the Shevaroy Hills. They were all undertaken with the view of filling gaps in the herbarium, and continuing the botanical survey. Particulars with reference to these expeditions, and the numerous specimens collected, are given in appendices to Mr. Thurston's report.

SOME remarks upon the practicability of destroying prickly-pear (*Opuntia Dillenii*) by means of the cochineal insect, are made by Dr. Bourne in an appendix to the report referred to in the foregoing note. Dr. Bourne points out that the historical evidence weighs entirely against the practicability of destroying prickly-pear by the cochineal insect. There seems to be no doubt but that the cochineal insects and the cacti are all introductions, and the net result has been that the yellow-flowered cactus has thoroughly naturalised itself, while the cochineal insect has just managed to struggle on here and there. There is evidence that cochineal insects were introduced five times between 1795 and 1883, with a view to the establishment of the cochineal industry in the country. In 1807 Government offered a reward of 2000*l*. for its successful introduction. It never became thoroughly established. It was, however, possible that, although a fine variety of the insect best for industrial purposes would not flourish, a wilder variety might become more or less naturalised. This has occurred to a small extent, and the idea of utilising this to destroy prickly-pear has been from time to time put forward. Dr. Bourne's investigations, however, show that it is impracticable to destroy prickly-pear by the so-called "wild" variety of the cochineal insect; and even if the scheme were practicable, he doubts the advisability of encouraging the development of an insect which might eventually become an infinitely greater pest than the prickly-pear.

A CATALOGUE and price list of the papers of the late Prof. E. D. Cope, arranged chronologically, with a price list of plaster casts, has been issued by Mrs. Cope, Haverford, Pennsylvania, U.S.A., who offers the papers and casts for sale.

TWENTY-FIVE papers on diseases of children will be found in the ninth volume of *Transactions* of the American Pediatric Society, edited by Dr. Floyd M. Crandall, and just published. The address of the president, Dr. Samuel S. Adams, deals with the evolution of pediatric literature in the United States.

A NEW edition of Babington's "Manual of British Botany" is in preparation by Messrs. H. and J. Groves. The first edition of this work was published in 1843; the eighth in 1881. It is hoped that the forthcoming edition—the ninth—for which the late author had accumulated many notes, may be ready early in next year.

DR. F. KRANTZ has issued a good catalogue (printed in German, French, and English) of minerals and geological specimens which he has in stock at the Rheinisches Mineralien-Contor, in Bonn. The catalogue contains particulars as to many collections of minerals arranged for purposes of instruction, and also for use with specified text-books of mineralogy. Lists of instruments and appliances used in the examination of minerals are also included.

THE additions to the Zoological Society's Gardens during the past week include two Red-sided Eclectus (*Eclectus pectoralis*, ♂ ♂) from New Guinea, presented by the Chevalier Angelo Luzzati; two Undulated Grass Parrakeets (*Melopsittacus undulatus*, ♂ ♀) from Australia, presented by Mr. A. J. Finch; a Booted Eagle (*Nisaetus pennatus*) from Southern Spain, presented by Captain T. E. Marshall, R.A.; two Tawny Owls (*Syrnium aluco*), British, presented by Mrs. Borrer; a Red-fronted Amazon (*Chrysotis vittata*) from Porto Rico, presented by Mr. G. A. Phillips; a Cereopsis Goose (*Cereopsis novaehollandiae*) from Australia, presented by Sir Cuthbert Peek, Bart.; two Gold Pheasants (*Thaumalea picta*, ♂ ♀) from China, presented by Mr. W. A. Upton; two Red-bellied Wallabys (*Macropus billardieri*, ♂ ♀) from Tasmania, presented by Major C. J. Urquhart; a Red and Yellow Macaw (*Ara chloroptera*), a Blue and Yellow Macaw (*Ara ararauna*) from South America, presented by Mr. W. Murray Guthrie; two Vulpine Squirrels (*Sciurus vulpinus*, ♂ ♀) from North America, a Slaty-headed Parrakeet (*Palaeornis schisticeps*) from Northern India, deposited; a Hyacinthine Macaw (*Anadorhynchus hyacinthinus*) from Northern Brazil, a Hobby (*Falco subbuteo*) from Holland, purchased.

OUR ASTRONOMICAL COLUMN.

THE ANDROMEDES.—As regards the return of the Andromedes, there is every reason to believe that by this time the shower will have passed by the earth's orbit. Brilliant displays were observed in 1872 and 1885, on November 27 in each year; and it would naturally be inferred that on the same day of the present year, which corresponds to an equal interval of time, a like occurrence should take place In 1892, however, the earth passed through this stream on November 23, and it has been computed that this recession of the node was caused by the perturbations of Jupiter, which were responsible for this difference of four days. If the observations made on the 23rd have indicated that this date is somewhat too early, observers should be careful to watch on the following nights, for, after all, the exact time of reappearance cannot be definitely foretold. The radiant point of this shower is in Andromeda ($25^\circ + 43^\circ$), and, therefore, at this time of the year at a great altitude. Unlike the Leonids they move slowly, as they have to overtake the earth in her movement round the sun.

A close watch on the night of the 22nd was kept at the Solar Physics Observatory, South Kensington: but the usual fog made its appearance at about 9 p.m., and became thicker towards midnight. Altogether *three* meteors were seen between 8.30 p.m. and 12.15 a.m., but none of these were Andromedes.

THE PLANET JUPITER.—The markings on Jupiter, which are involved in the dense atmosphere around him, have been subjected to minute observations for many years, and it is now that we are beginning to learn something of the circulation in operation on that planet. That the atmosphere does not rotate homogeneously has for many years been known, and the movement of the great red spot may be given as an instance of this irregularity. Mr. Stanley Williams, a faithful observer of Jupiter, showed clearly in 1888 that there existed a swift southern current which extended from latitude -37° to -55°. In a more recent communication (*Astr. Nach.*, No. 3528) he has published the results of observations of two southern spots within this zone which were visible, one in 1890 and the other two years later. The object of these observations was to investigate whether such a current is a permanent feature of the planet or not, and to trace from year to year the variations that may occur in the velocity of its motion.

Without entering into the details which are given in his article, we will limit ourselves simply to his results. The following table shows the periods of rotation obtained, the first being an observation by Prof. C. A. Young in 1886 of a small white spot in latitude 50° south.

Year.	Limit of lat.	Rot. period. h. m. s.
1886	-50°	9 55 11·1
1888	-37° to -55°	0·9
1890	-36° to -45°	6·7
1892	-32° to -39°	8·4

A glance at the figures in the last column shows that this southern current is not only a permanent feature of the planet, but that its velocity is not constant. As regards the limit of the zone in which this current exists, we are told that the current may extend further southwards, and perhaps even to the pole itself.

We hope that Mr. Stanley Williams will continue his observations in this region, and settle this question of limit, which is important in the light of the general atmospheric circulation of this planet.

THE PERSEIDS OF 1898.—In August last the weather was so favourable that at a great number of places observations of the Perseids were successfully made. A not unimportant feature of the display was the large number of meteors that did not radiate from Perseus at all, and this fact is very clearly brought out in the description and chart of the observations made by Messrs. Vacca and Senouque on the nights of the 10th to the 16th (*Bull. Soc. Astronomique de France* for November). It must be mentioned that at Paris, where these observations were made, the night of the 10th was not very clear; so the majority of the observations were made on the following nights.

An examination of the diagram shows several distinct radiant points, not only in Perseus, but in Cassiopeia, Cygnus, and the Great Bear.

Another set of interesting observations, made by M. Fournier, is published in the same journal, and contains also a reproduction of a chart, showing the trails recorded. This, however, is restricted to the night of the 10th, which was beautifully clear at the place of observation, and the chief radiant point deduced is well defined near η Persei. Out of sixty meteors observed, thirty-nine were Perseids, five or six sporadic, and some others apparently radiating from Cassiopeia.

ASTRONOMICAL SOCIETY OF WALES.—The last two monthly numbers of this Society's publication, the *Cambrian Natural Observer*, show that interest in astronomical phenomena is by no means at a low ebb, but rather verging on a spring tide. The October number contains some interesting notes about Gruithuisen, who was for some time editor of the *Jahrbuch*. His great speciality was a study of the lunar features; and although ridiculed, he was nevertheless "an assiduous and careful observer." Mr. Denning contributes some notes on meteoric fireballs, and describes how observations should be recorded. He gives, also, the right and the wrong way of recording them, or rather, we should say, the useful and the useless, from published examples, and we cannot help quoting them as guides to future recorders.

"On June 10, 1891, I saw a beautiful phenomenon. Suddenly at the zenith, east of the Great Bear, shone forth a yellow globe like Venus at her brightest. Dropping, somewhat slowly, it fell obliquely southwards. As it passed in its brilliant career, it lighted up its dusky path with a glorious lustre. When it had descended about half-way down towards the horizon, it burst into a sparkling host of glorious fragments, each dazzlingly shot over with all the hues of the rainbow."

The useful record was as follows:—

Date and time.—1892 December 12, 11h. 22m. G.M.T.

Object.—Fine meteor, nearly = Jupiter.

Path.—$55^\circ + 41^\circ$ to $45^\circ + 20^\circ$; length 22°.

Duration of flight.—1·2 seconds.

Colour.—Bluish-white.

Appearance.—Brightest in latter portion of its path, where it left a white streak for about one second.

Probable radiant.—ϵ Ursae Majoris.

The November number is especially a "meteor" number, and contains information on the observation of these bodies by Denning, Johnstone Stoney, Carslake Thompson, &c.

PHOTOGRAPHIC PLATES AND THE SPECTRUM.—In laboratories and observatories where a study is made of gaseous and metallic spectra by the aid of photography, it is important to make use of the differences between the sensitiveness of the numerous photographic plates which are obtainable. For that particular part of the spectrum which may be under investigation, it is always desirable to employ the greatest photographic action possible, and this can only be done by preparing plates which are most sensitive to this region. A very interesting comparison of the sensitiveness of various plates for the different regions in the spectrum is given by Mr. E. Sanger Shepherd (*Journal of the Camera Club*, vol. xii. No. 150), in an article on the photographic reproduction of paintings; and curves are added, showing clearly how each of the plates behave.

Comparing the Cadet spectrum plate and the Ilford chromatic plate, the former gives action beyond the D line, whereas the latter ceases at the D line; there is very little red sensitiveness, which is perhaps the worst feature of the plate, and there is a gap in the green. Lumière's panchromatic plate has extreme red sensitiveness; but except for a small gap, in the green it is sensitive all through the spectrum. In Lumière's "B" plate the sensitiveness in the red is very considerable and more extensive than in the plate preceding, but there is a very long gap in the green. Edward's snap-shot isochromatic plates have considerable sensitiveness in the green and yellow, and a little less in the red; the curve is here much smoother, and not subject to such great changes.

In the Cadet lightning spectrum plate we have extreme sensitiveness from the blue to the yellow, and yet sufficient red sensitiveness for many purposes. Considering the whole spectrum, it seems to be the best plate for uniformity throughout, and the small gap in the extreme red makes it possible to use a considerable amount of light for developing.

Although it is not absolutely necessary, it is always more convenient to develop in a room lighted sufficiently to see how the image appears. Many photographers do not pay sufficient attention to the purity and colour of light that is admitted. The gaps in the sensitive curves point out clearly those rays which have least action on the plate, and which should therefore be

used as light filters. Thus for Lumière's "B" plates we must have a bright chromium green, a deep pot-green glass, together with aurantia; while for Lumière's "A," we should use a red light consisting, for instance, of aurantia, naphthol yellow and fuchsin films. For Thomas's plates a faint green or a fairly bright red glass with a strong tint of aurantia dye might be employed. Edward's snap-shot isochromatic and rapid spectrum plates require the quality of the filter light to be very pure.

THE CHEMICAL SOCIETY'S BANQUET TO PAST-PRESIDENTS.

REFERENCE has already been made to the banquet given on November 11 to Sir J. Henry Gilbert, Sir Edward Frankland, K.C.B., Prof. W. Odling, Sir Frederick Abel, Bart., K.C.B., Prof. A. W. Williamson, and Dr. J. H. Gladstone, Past-Presidents of the Chemical Society, who have been Fellows of the Society for fifty years or more. The idea of expressing in this way the high regard in which men of science hold the work of these distinguished chemists was an excellent one, and it was well carried out. The large number of congratulatory telegrams and communications received on the day of the banquet from every country where the science of chemistry is cultivated showed that the whole civilised world was in sympathy with the object of the banquet. Communications were received from France, Holland, Belgium, Germany, Sweden, Russia, Austria, the United States, and several other countries. Prof. Friedel wrote: "I should have been happy to associate myself with the Chemical Society in doing honour to these veterans of science. I have the honour to be the friend of most of them, and the beneficent action they have exerted on Chemical Science cannot be esteemed too highly. They form the finest phalanx of the Fathers of our science which exists in any country. With these sentiments you will understand the liveliness of my regret to be able to take part from afar and in spirit only in the honour paid them." At a meeting of the Russian Chemical Society the following was passed: "That the Society avail itself of the exceptional opportunity of being able to congratulate conjointly Sir Joseph Henry Gilbert, Sir Edward Frankland, Prof. Odling, Sir F. A. Abel, Dr. A. W. Williamson, and Dr. J. H. Gladstone, whose distinguished services during half a century stand out as a model for all investigators in chemical science, and also express the wish to see the further results of their labours in the annals of science for many years to come." A telegram from the German Chemical Society contained the message: "The sister Society sends both Jubilee congratulations and greetings to the Jubilee celebration of the Presidents of the Chemical Society, Gilbert, Frankland, Odling, Abel, Williamson, and Gladstone." These messages show that the distinguished men to whom the banquet was offered are held in the highest esteem in all places where chemical studies are carried on.

We regret that the limitations of space will not permit us to print the speech in which the President, Prof. Dewar, who occupied the chair at the banquet, alluded to the work of the six Past-Presidents, nor can we find room for any speeches other than those in which these distinguished men replied to the toast in their honour.

Sir J. Henry Gilbert said:—"After the extremely flattering and eloquent terms in which our President has referred to the work of the six Past-Presidents of the Society who are so highly honoured to-night, it is surely a difficult task to say anything in response. I feel that any words of mine would be entirely inadequate; and I must, I think, fall back on what I was intending to say, and give a little personal history of the early times of the Society. You are aware, most of you, that I am to night in the position of the senior of the Past-Presidents, in consequence of the death of Lord Playfair. He was, as you know, one of the founders of the Society, and, before he died, the only survivor of those founders. I myself came in within three months of the foundation, and so had some knowledge of the Society's early doings. In fact, before I was really admitted to the Society, under the influence of the late Professor Graham, I undertook the translation of a paper by Redtenbacher and Liebig on 'The Atomic Weight of Carbon,' and that paper occupies eighteen pages in the first volume of the Society's 'Memoirs.' I should say that, less than a fortnight ago, I received a letter from Lady Playfair, just before she left to visit her friends in America, in which she said with what interest he had looked forward to being present at the banquet appointed for June—but that was not to be. I first made the acquaintance of Playfair in Liebig's Laboratory at Giessen, the year before the establishment of this Society, that is, in 1840. Playfair was at that time very busily occupied in translating the memorable work of Liebig, 'Organic Chemistry in its Applications to Agriculture and Physiology'; and before the session was over he left for this country with Liebig, who was to present the substance of that work as a report to the British Association at Glasgow in September. You may be interested to know who there were from this country in Liebig's laboratory at that time. Besides Playfair and myself, there were Dr. William Allen Miller, afterwards professor of chemistry at King's College; Dr. Stenhouse, who has contributed so much to the *Journal* of this Society; Dr. Angus Smith; and, lastly, Dr. Edward Schunck. He and I are, I believe, the only survivors of that time among those from England who were with Liebig then. Of the Germans who were there, some of the names you will probably remember. There were Heinrich Will, Varrentrapp, Redtenbacher, Hermann Kopp, Scherer, Bromeis, Boeckmann, and others, of various nationalities; but I believe that not one of these survives at present. Schunck joined the Society early in 1842, and he from that time to this has devoted himself to scientific investigation. He built a laboratory, and a museum devoted especially to specimens of organic bodies, in his own grounds on the other side of Manchester, where he still lives. He was, in fact, the oldest member of the Society, I believe, except Playfair and myself. He has worked indefatigably ever since; but I am very sorry to say he is not able to be here to-night, having had an attack of bronchitis, which renders it impossible, though it would have given him great pleasure to be present. Referring to that time at Giessen, I may say that Playfair, Stenhouse, and myself, each took our degree then; and Playfair, though joining with us, having gone with Liebig, the responsibility was left with Stenhouse and myself to give the usual supper to the other students of the laboratory, and a few distinguished guests, among whom was Bunsen, who was then at Marburg; and who, I am glad to learn from Sir Henry Roscoe, is still well. Stenhouse was much my senior. We had a large and lively party, but Stenhouse did not enjoy that sort of thing very much, and when the last bottle of champagne was opened, he said: 'Now, Gilbert, I shall leave you to it,' and away he went. That was, however, not near the end of the evening. They stayed a very long time, and we did not exchange the smoky atmosphere of the supper-room for the clearer air outside until early morning. We then went round the boulevards of the little town, the Germans singing students' songs, and coming in time to the hotel where Stenhouse lodged, we serenaded him from the outside. Then some one tried the door, and finding it unfastened, the whole party went up, lighted candles, and serenaded him in bed. Next morning there was a very capital caricature brought out, showing Stenhouse's rather long nose pointing in one direction, and his longer nightcap in the other. But this is enough of this kind of history, and I must now turn to rather more serious matters. It was in 1843 that I became associated with Mr. (now Sir John) Lawes in agricultural investigation—a collaboration which has now extended over more than fifty-five years. As you all know, however rude may be some of the methods of the art of agriculture, the investigation of the principles underlying its practices involves a wide range of scientific inquiry. It involves the chemistry of the atmosphere, of the soil, of vegetation, and of animal life and growth. That is to say, besides chemistry, it involves meteorology, botany, vegetable physiology, and animal physiology, to some extent. It is impossible to be a specialist in so many subjects, particularly in these days, and I can only say that in venturing to deal with these other branches of science we have taken great care to avoid mistakes. The wide range of the investigations must be accepted as some explanation of the fact that we have not contributed more of the results to the Chemical Society. Many of them being connected largely with other branches of science, have been recorded in other than purely chemical journals; whilst those having a more directly practical bearing have been published in the *Journal* of the Royal Agricultural Society, or in other agricultural publications—the Rothamsted papers now numbering considerably more than 100. But we feel that, however long or short may be the time that we shall still work

together, we shall perhaps have done as much in opening up as in solving problems ; and that we shall certainly leave plenty for our successors to do. In conclusion, considering that there still remain five of your honoured guests to speak, this is all I will say of my own career, and I will only now ask you, Mr. President, the Council, and the Fellows of the Chemical Society, to believe that I esteem very highly the great honour you have conferred upon me to-night."

Sir Edward Frankland—"Allow me to thank you, Mr. President, and the Council of the Chemical Society for this delightful entertainment which you have prepared for the Past-Presidents who have attained Jubilee rank. It was a generous, unique, and happy idea, which I feel sure we all heartily appreciate, not only as we sit at your hospitable board, but also when we reflect on the kind feelings which led to the conception of that idea. There used to be a phrenological organ entitled 'love of approbation,' and whether there is or is not a part of the brain told off to perform this function, I trust that chemists are not behind the rest of humanity in appreciating such an honour as you have conferred upon us on this auspicious occasion. Nothing could be more agreeable than thus meeting so many colleagues who are worthily keeping up the high reputation of the Chemical Society. There is but one drawback to our enjoyment, and it has been very feelingly alluded to by Sir Henry Gilbert, namely, that one who so recently stood at the head of our Past-Presidents should not still be present amongst us. In the lamented death of Lord Playfair, chemistry and science generally have sustained an immeasurable loss ; for he was a binding link between science and the State, always ready to fight for the cause of truth against prejudice and ignorance, and never ceasing in his efforts to bring home to our rulers the vast importance of the applications of science to the progress, health and prosperity of the nation. As one of his first pupils, and after a life-long friendship, I may be permitted to testify that his energy in this cause was prompted by sincere convictions and not by political exigencies. Had Playfair lived a few months longer, we should never have had the misfortune to make the acquaintance of that new variety of *Homo sapiens* the 'conscientious objector,' who is just now giving so much trouble to our magistrates. This is not a time to sketch, even in merest outline, the epoch-making work of the Society, but I may at least state my conviction that it will be found, on comparing the volumes of our *Transactions* with those of the corresponding societies of other lands, that, considering the number of workers in each case, England is not behind any other nation in research work, and this in spite of the almost total absence of that lavish State aid which nearly every other civilised nation enjoys. In view of the vast number of discoveries pouring out from chemical laboratories, I hear it suggested that the day is not far distant when there will be nothing left to discover, when all the elements in the cosmos shall have been captured and fitted into the periodic system of Newlands and Mendeléeff, when there is not one more gas in the atmosphere left to be detected, and every element and group of elements shall have its ortho-, para-, and meta-position assigned to it. What will then remain to be done? Fortunately for investigators, we shall still be only as children gathering pebbles on the shore of the great ocean of knowledge. As yet we have only found the big boulders. To change the metaphor, chemistry now occupies the position of geography a century ago. The enormous number of chemical compounds are like so many islands, their latitude and longitude ascertained with precision, but on which the foot of man has not been put down, whilst their animals, plants, and minerals have never been exploited. When the ideal state of knowledge has been attained, chemists will perhaps find time to explore this vast archipelago, in which, there is no doubt, many interesting discoveries await those who shall undertake the task. Who can set a limit to the usefulness of these explorations? Even the most unpromising compounds may turn out valuable prizes! When aniline, chloroform, and carbolic acid were discovered, who could have predicted the revolutions in the arts and surgery which these bodies were destined to produce! They were but as desert islands until they attracted the attention of Hofmann, Perkin, James Simpson, and Lister. As chemists, I believe we have a noble future before us. Chemistry is distinguished from all other branches of knowledge as the helpmate of nearly every other science. The geologist, the botanist, and the physiologist find no thoroughfare unless they call in the help of the chemist. As soon as the physicist breaks into a molecule, he is trespassing on our domain. The bacteriologist has found that it is not the waggling of the tail of a pathogenic microbe that is the most important feature of its history, but that the chemical compounds which it secretes demand his closest attention. Even the astronomer has already to sit at the feet of the chemist! Thirty-three years ago, when our worthy President was but a youth, there was once a dinner party composed chiefly of chemists held at the 'Albion.' A few are still living—among them being Sir F. Abel, Prof. Odling, and myself. In an after-dinner speech on that occasion, my friend Abel is reported to have expressed himself in blank verse as follows (I hope he will forgive me, at this distance of time, for appropriating his words to my own use):

"'Looking to right and to left, I see many faces around me,
Faces so old and familiar I feel once again at the College,
Testing, as in former times, for chlorine with nitrate of silver,
Gazing with youthful delight at crystals just hatched in a beaker,
Yearning o'er aniline drops distilling from crystal alembic.
O! my dear friends, one and all, we have toiled up a difficult pathway!
Some are low down on the hill, and others are near to the summit.
Let us remember the past and forget not our absent companions;
Fortune may come to us all; but youth will return to us never!'"

Prof. Odling:—"I do not know that I can better commence the few observations I propose to make to you than by following in the wake of my predecessor, Sir Edward Frankland, and saying that it is no less a great pleasure than my bounden duty to express to you, Mr. President, and to the Council and Fellows of the Society, my heartfelt thanks for the great compliment that you have paid to my colleagues and myself on this long-to-be-remembered occasion. Speaking, however, for myself personally, it is not the first time that I have had evidenced to me the kindly feeling of the Chemical Society. On the occasion of my retirement from the Secretaryship in 1869, I had also the special honour done me of being entertained at a dinner by the Society; and I also received a further token of their goodwill in the form of a capacious loving cup of no inconsiderable value in itself, but of far greater value as a perpetual mark of the kind feeling towards me of those with whom I had been for so many years so intimately connected. Those of us whom you entertain this evening have for a long period of time, as Sir Henry Gilbert and Sir Edward Frankland have already remarked, been associated with one another in common pursuits and enjoyments; and if there is one thing more than another that enhances to me the gratification of this meeting, it is the pleasure of finding myself associated still with my old friends and colleagues, Gilbert and Frankland and Williamson and Gladstone, and my earliest friend of all, Sir Frederick Abel. We have been concerned with one another in a large number of undertakings, and for a long period of time have been accustomed to hear one another's voices as well upon festive as upon scientific occasions. But we have not been accustomed to hear them in exactly the order they have been arranged for this evening. I have always looked upon myself, not as a precursor, but as a follower of Williamson. It has been my pride to reckon myself one of his adopted pupils—a disciple of his ideas more perhaps than many of those who were his actual pupils. He was always very decided in his notions. Sometimes, indeed, I turned a little restive, but was always soon pulled up into form again—sometimes more abruptly, perhaps, than was quite agreeable at the moment. At one time I laboured under the sad suspicion of being a little unsound as to the Atomic Theory. Well, perhaps I was not altogether so stalwart in its defence as I ought to have been; but I can assure you that I was never really guilty of so reprehensible a heresy as that which was attributed to me.

"You are doing us honour here this evening not so much, or not only, as students of the science of chemistry, but also as Past-Presidents of the Chemical Society. As ancients of that Society, we may all of us perhaps be permitted to talk a little about ourselves without incurring the imputation of egoism, and also to talk a little about old times without incurring the reproach, after our fifty years' fellowship, of senile garrulity. At the period during which I acted as one of the Secretaries of the Society, and my colleague, Prof. Redwood, concerned himself mostly with the business department of our affairs, the Chemical Society had not developed very far its function as a publishing agency, and as a consequence, even for that little prolific time, we did not get our fair share of important papers communicated at first hand to our meetings. But if we did not receive elaborate communications, we enjoyed the benefit of elaborate discussions; and there was no new class of compounds,

no newly propounded doctrine, no new reaction which was not submitted to our keen examination and controversy. The subjects of several of those controversies, and even the fashion of them, still linger in one's memory. I need scarcely say that chemical theory came in for a large share of our attention. The molecular weights of water and carbonic acid, the atomic weights of oxygen and carbon, and, above all, the then newly introduced idea of polyatomic radicles, were keenly discussed. We were a little too late for the interesting question as to whether compound radicles could possibly be oxygenous; but still, radicles were predominant at that time in chemical science, and reigned with undisputed sway over the whole domain of organic chemistry. One cannot but reflect how fleeting has been their reign. The doctrine of radicles has now sunk to an entirely subordinate position in chemistry, not unlike, may I venture to say, the subordinate position into which radical doctrines have fallen in a different sphere. There was one particular controversy I remember very well, and am sure Frankland will remember also. It was of this kind: whether the bodies called ethyl and methyl were really ethyl and methyl at all, or something else. Well, a question of that kind in those unsophisticated days had to be answered definitely by a plain aye or no. There was no loophole for escape or trimming, no possibility of saying that the one answer was just as true as the other, according to the point of view taken; nor was there existent in that period of innocence, for the solution of yet more puzzling problems, what we know now by the name of tautomerism, by which we learn that a body is, and at the same time is not, what it is alleged to be: that it is sometimes one thing and sometimes another, and sometimes both together, and yet preserves its individual chemical entity. In those days the principal provider of chemical material for our meetings was far and away Hofmann. He was in the habit of sending his multitudinous papers to the Royal Society for publication; but he gave us the advantage of his presence and his personal disquisitions; and I would appeal to all in this room who had the advantage of seeing him to say if they can possibly forget his appearances at the blackboard of the Chemical Society, and the enthusiasm and lucidity of his expositions of different points of chemical constitution, enlivened as they were by that extraordinary display of vivacity so inconsistent with the quiet phlegm we are in the habit of attributing to those of his nationality. But, despite the productiveness of Hofmann, still there were evenings on which something else was required; and then it behoved the Secretary to search far and wide for material to bring before the meeting of chemists who, with Greek-like avidity, were always clamorous for 'some new thing.' At that period the activity of the Giessen school was somewhat on the decline, and we looked for novelties in chemistry, as for novelties in mantles and millinery, to Paris. We had for our consideration the acidic ammonias of Gerhardt and the diatomic glycols of Wurtz, and the production of alcohol without the aid of either sugar or yeast, by Berthelot; and many other remarkable contributions to the knowledge of the day. But our friends across the water, with so much—so very much—justly due to them, nevertheless did manifest now and then a tendency to appropriate to themselves what did not altogether belong to them; and in this the country of Black and Priestley and Cavendish and Dalton and Davy, we were astonished one fine morning at being informed that 'la Chimie est une science française.' But even with the productiveness of Hofmann and the searchings of the Secretary, it did sometimes happen that our bill of fare was a little meagre. But what of that? Those were supper-eating days, and a meeting rendered brief by want of pabulum could always be supplemented by a prolonged and substantial, and, I may add, a musical, meal at a then well-known resort not far from Covent Garden; and when it happened, as it did sometimes, that our proceedings were not so exhilarating as they should have been, when divine philosophy had proved less charming than its wont, Hofmann, despite the abundant supply of tea and coffee of excellent quality, would, with a burst of inspiration, thrust forth his right hand and say: 'I will tell you, we will have a punch!

"But the Chemical Society has a future to look forward to, as well as a past to look back upon. At the Jubilee of the Society some seven or eight years ago, it devolved upon me to give an account within the short period of a quarter of an hour—I believe I occupied twenty minutes—of the progress of chemical science during the preceding fifty years. But to-day is also a Jubilee or almost so, the Jubilee of our incorporation by Royal Charter, which, in the then days of our insignificance, Playfair did so much to obtain for us. Now, on this diamond Jubilee, I ask you how many minutes will you give me to lay before you a forecast of the chemical progress that may be expected to take place within the next fifty years? I will only venture to say that, judging by the number and activity and intellectual gifts of the workers of the present day, we may feel assured that the achievements of English chemistry and the progress of the Chemical Society in the past will be as a mere nothing to the brilliancy which they will attain to in the future."

Sir Frederick Abel—"Sir Edward Frankland has out of his vast stores of knowledge recalled a fact of which I confess I was ignorant, that in years past I indulged a poetic fancy. I only wish I might now be inspired in order to find words to express on behalf of myself and my old friends our appreciation of this glorious reception which you have given us. The Chemical Society is endeared to me in many ways. Among the epochs of a somewhat long career of ceaseless activity, that which connected me intimately with the work of the Society is one of those which I recall with the greatest pleasure and satisfaction. And it so happens that the years of my connection with the Society in various functions were years in which some of the most memorable events in its annals occurred. As Treasurer, it was my privilege to arrange with the illustrious chemist and brilliant orator, Jean Baptiste Dumas, for the delivery of the first of those memorable lectures which were given through the agency of the Chemical Society in honour of the memory of Michael Faraday. While I was Treasurer, the volume of the *Journal* of the Society, which was then of modest and slender dimensions, nurtured by well digested extracts from foreign journals, speedily gained proportions unwieldy in character, so unwieldy, in fact, that the one volume split up into two before long. In the first year of my Presidency, the Research Fund, which was initiated in a modest manner by Mr. Thomas Hyde Hills, was placed upon a firm and substantial basis through the generosity of one of the most respected of the Society's original members, Dr. Longstaff; and in the second year in which I held that office, the somewhat revolutionary agitation which was persisted in by a not unimportant section of the younger Fellows of the Society, an agitation which, by the way, has been imitated since—led to earnest deliberation and consultation between the Council and some of its chosen members outside the Council, which resulted in the birth of an institution now flourishing exceedingly, which has become the guardian of the best interests not only of the chemical profession but also of the public. I of course allude to the Institute of Chemistry of Great Britain and Ireland. When I look back to the early days when I first owned the proud title of F.C.S., and remember my attendance, in a small room at the Society of Arts, at the meetings of the Chemical Society, presided over in succession by William Brande and Phillips, the business being managed by George Fownes and Robert Warington, the founder of the Chemical Society, and the funds not very cleverly handled by dear old Robert Porrett, one of the most prominent forms that appears in my mind's eye is that of the favourite pupil of Liebig, my venerated master, Hofmann. In the very first years of the Society, Hofmann became the very life and soul of it. He was beloved by his English brethren directly he came among them, and for years he was by far the most prolific contributor, either himself or through his pupils, to the volumes of the Society. Pardon me if I have been tempted into reminiscences; it is difficult to avoid it at such a gathering as this. The welcome you have given to the veteran Past-Presidents will remain in their minds to their last day as one of the great joys of their lives. To the many old friends and colleagues whom I see around me—Past-Presidents who, as men of science, hold positions second to none, whose names are familiar as household words—to them I can wish no higher gratification than that they may live to experience the satisfaction of such an entertainment, and of such a graceful appreciation of their work, as has been the lot of your old Past-Presidents to-night."

Prof. A. W. Williamson—"I thank you, Mr. President, most heartily for the kindly words you have uttered in relation to me, and to my efforts for the advancement of chemistry. It is an immense satisfaction to me to see a man of your talents and vast acquirements placed in so influential a position as that which you so worthily occupy. But whilst thanking you I am

bound to confess that I have heen for some time past a most unworthy member of the Chemical Society It happened that after a good many years of work in our Society, I had other matters of such importance claiming my time and attention, that I was unable to continue to work amongst my colleagues and friends in the Chemical Society.

"Before I came over in 1849 to work at University College, I had become acquainted in the Giessen Laboratory with that most remarkable man, August Wilhelm Hofmann, and I may mention a characteristic incident illustrating his earnest and steadfast devotion to his science. He had for a considerable time been working at derivatives of aniline, and in order to carry on these researches as effectively as possible, he prepared by the action of caustic potash on indigo about some two gallons of aniline. The product was placed in a big bottle on the mantelpiece in his bedroom, and the story goes that he used to stand and gaze at it for some time every morning and evening, and gloating over it with delight would think, 'what a number of splendid products I shall make out of this aniline!' The energy and devotion with which he followed up his work on the derivatives of aniline at the expense of many other researches which he might with advantage have followed up was such that he came to be talked of as the great worker on aniline, and Sir Benjamin Brodie somewhat prematurely wrote his epitaph in the following words, 'Hic jacet Aniline' His researches extended, however, at an increasing rate into other and wider departments of chemistry, and his energy and enthusiasm were such as to make him the leading explorer in the domain of organic chemistry. Berzelius had been for a lengthened period the one great man in the domain of inorganic chemistry, which was the only part of the science which had been explored to any appreciable extent. When I saw the vast piles of knowledge which Hofmann was so rapidly accumulating in the new domain of chemistry, I felt, and ventured to say, that his masterly labours entitled him to be called the Berzelius of Organic Chemistry. I happened to be present at a meeting of the Chemical Society at which a young chemist read a paper in the presence of Hofmann on some theoretical matters of importance which had already engaged the attention of distinguished chemists. Hofmann did not enter into any particulars of the paper, but he gave vent to an outburst of heartfelt delight at the simple narrative which had been read. There are various incentives to work, but the most potent incentive to earnest and efficient work is probably the example of a man like Hofmann, whose whole delight lay in mastering the truths of science, and in learning more and more particulars of the order of nature, and Hofmann possessed that power in a most eminent degree.

"We see in this grand hall an assemblage of chemists known by their earnest labours and valuable discoveries, and we are honoured by the presence of men of the highest distinction in other branches of science, as well as of leaders in the learned professions. It might not be unreasonable to believe that enthusiastic delight in the triumphs of chemical research is duly represented by some of the guests in this hall, and that the lively conversation which has been going on may not relate merely to high questions in jurisprudence, medicine, or legislation, but that some samples of chemical enthusiasm may reach the ears of the learned representatives of other professions.

"I feel sure that at a future time we shall all look back with the highest pleasure upon this delightful evening, which we owe to the kindly exertions of our President and other leading members of the Society."

Dr. John Hall Gladstone—"It is a pleasant thing to look on the faces of so many friends with whom one has worked in olden times, with whose works one is well acquainted. Though, of course, there are many at the present time who come into the Society, and whom I can look to as budding philosophers: unfortunately, I do not know their names so well as their faces. The pleasure is not merely because we call ourselves chemists, but because there is a bond of union between us arising from the desire of discovering the wonderful secrets of the great cosmos of which we ourselves form part. There is a great difficulty in speaking to you this evening, because so much that I should have liked to say has already been said by previous speakers. Still there are one or two things which, if you will permit me, I should like to bring before you. First of all, in your too flattering description of myself and of my work—which makes me rather ashamed to stand up and speak—there was a point which I think calls for remark, and so I must venture upon that which characterises the speeches of all of us, a certain amount of early autobiography. I was exceedingly fond of science from a little child. My favourite science was geology, and also what could be seen in the microscope—infusoria, and other little objects we have heard of in later times. But, in choosing a profession, my father said geology was not a promising career, and recommended chemistry. I knew very little about it, but went to University College and studied under that admirable teacher, Professor Graham, and afterwards under Liebig. I suppose it was from Graham that I acquired the taste for the physical side of chemistry and its connection with heat, light, electricity, and other forces of nature. I looked out for a scientific position, and lectured at St. Thomas's Hospital for some time, made analyses, and considered myself a professional chemist It may be that circumstances have caused me to sink into the position of an amateur chemist, but my first intention was that of following chemistry as my profession in life. It has not been necessary to continue that; and I have had this advantage, that I could always keep in my laboratory a good, trained assistant, and thus, whilst I was engaged in other works and ways, and in endeavouring to extend the knowledge of chemistry and elementary science in our primary schools, the work still went on more or less under my immediate direction. I should like to have said something about the progress of chemistry during these past fifty years; but the subject is so enormous, and you yourself have touched upon it to such an extent and so well, that I need only allude to the fact that this great change of volume of chemistry has caused it to be necessary that we should specialise. Specialisation has its advantages, but also its disadvantages. One danger is that we may become narrowed in our views. So it would appear to be best to have a home somewhere or other, but to make occasional excursions in the neighbourhood, and take summer holidays so as to get our nerves braced up to work again at our own pet subjects. I must not touch upon other points, such as the relations of the physical forces to chemistry, or its useful applications, and the great value of chemical research for the welfare of mankind. These are subjects too large and important to enter upon at this late hour. It seems to me that while we are always increasing the mass of knowledge we possess, the space which we see to be bright becomes larger and larger, but there is beyond a dim nebulosity. It is our work to bring from that nebulosity something into the bright space, so that it becomes the property of the human race. But there is beyond this a region which we do not understand—infinite as far as we know—and our object is to increase that which is knowable, in the firm belief that it will be for the advantage of our fellow creatures. While I feel thankful for the joy that I have had in taking some part in these discoveries, I cannot look to have much more time given me for carrying on this work of investigation; but still, there may be a few threads of old research I may gather up, and in doing so I shall be greatly encouraged by the kind remarks of this evening, and the way in which our work has been received by the friends gathered around us."

RECENT AND FOSSIL RHINOCEROSES.[1]

PROF. OSBORN'S palæontological work is so painstaking, and his material is so rich, that all interested in the study of the evolutionary and distributional history of those remarkable Peristodactyles which may be included under the general title of Rhinoceroses, cannot fail to welcome the appearance of the elaborate and well-illustrated memoir before us. As at present planned, the complete memoir is to consist of no less than seven parts, two of which are contained in the present issue; so that until the whole appears, a suspension of judgment in regard to many points is due to the author.

Prof. Osborn is of opinion that the Rhinoceros-like Ungulates may be divided into the three families of *Hyracodontidæ*, *Amynodontidæ*, and *Rhinocerotidæ*. And as this arrangement tallies fairly well with the date of appearance and disappearance, and also with the relative specialisation of its various members, the general principle may be adopted. It must not, however, be supposed that either of the first two families are exclusively ancestral types of the third, as many of their representatives tended to specialise at a comparatively early period, and took an evolutionary line of their own. Some, for instance,

[1] "The Extinct Rhinoceroses." By H. F. Osborn. *Mem. Amer. Mus Nat. Hist.*, vol. i. part iii., pp. 75-164, Plates XIIA-XX. (1898.)

developed into upland running types, which competed with the Horses and Ruminants of the plains; while others were more likely frequenters of marshes and river-banks, like many of the Rhinoceroses of the present day. Neither the Hyracodonts or the Amynodonts ever developed horns, and all the early species of true Rhinoceroses had weak, hornless nasal bones, so that in external appearance they were probably more like large-sized Tapirs than the well-armed animals with which we are now familiar.

"They did not interfere with each other," writes the author, "because each enjoyed a different local habitat while occupying the same general geographical regions. The Hyracodonts dwelt in the drier grassy plains. The Amynodonts frequented the river and lake borders. Up to the time of the extinction of these two related families, the true Rhinoceroses maintained a somewhat uniform structure, both in Europe and America, differing so far as we know in size rather than in proportions. Their dentition and their feeding habits were probably similar to those of the *R. bicornis* of Africa, and the *R. sumatrensis* and *R. sondaicus* of Asia, namely upon shrubs, leaves, and softer herbage. After the extinction of the rival families, however, there was naturally a tendency on the part of the true Rhinoceroses to enter the peculiar local habitats previously occupied by the Hyracodonts and Amynodonts, and they accordingly diverged into upland and lowland, short and long-limbed, brachydont and hypsodont types."

From this it will be evident that Prof. Osborn by no means confines himself to the dry details considered sufficient by so many palæontologists, but endeavours to give his readers a mental picture of the habits of the animals he so well describes. He next proceeds to show that the *Rhinocerotidæ*, or true Rhinoceroses, diverged into four sub-families. These are, first, the *Aceratheriinæ*, or Hornless Rhinoceroses; second, the *Diceratheriinæ*, or Transversely-horned Rhinoceroses; third, the *Rhinocerotinæ*, or typical Rhinoceroses; and, fourth, the *Elasmotheriinæ*, represented only by the huge *Elasmotherium* of Siberia. And he further shows that while the first and second of these, like the Hyracodonts and Amynodonts, are common to the Old and New Worlds, the third and fourth are exclusively Old World types.

In the New World the Rhinoceroses became entirely extinct at the close of the Miocene period; and this, although it is not mentioned by the author, is doubtless the reason they never penetrated into South America, which up to that date was cut off from North America. No reason can at present be assigned for the sudden extinction of the group in North America, seeing that a profusion of animals, adapted apparently for a warm climate, flourished there during the Pliocene; while the case of the Woolly Rhinoceros and the Elasmothere indicates that the Rhinoceroses themselves were capable of fitting themselves to withstand sub-arctic conditions.

Whether the group first originated in the Eastern or the Western Hemisphere, the author, perhaps wisely, refrains from discussing. In both regions they appear to have come into existence at approximately the same period; and in both, up to a certain stage, they seem to have undergone a parallel development. This, as in the case of the Horses, would seem to suggest that during the middle portion of the Tertiary epoch the connection between the Old and the New Worlds was much more extensive than a mere narrow bridge across Bering Strait. But, on the other hand, the existence of large groups like the Civets and Hyænas which never succeeded in travelling from the Eastern to the Western Hemisphere, is, so far as it goes, in favour of only a narrow connection in high latitudes.

As already mentioned, the author includes all the typical Rhinoceroses in a single sub-family or group. On p. 84 this group is correctly termed *Rhinocerotinæ*, but in the table on p. 121 it is renamed *Ceratorhinæ*, which is obviously wrong. As with the *Aceratheriinæ*, the author considers that the group may be divided into a Dolichocephalic and a Brachycephalic section. The former section is taken to include all the Pliocene and Plistocene Old World species, with the exception of the Pikermi *R. pachygnathus*; while the latter embraces the Miocene and recent Old World types, except the living *R. sumatrensis*. To this classification we must take one exception. In our opinion the African "White Rhinoceros" (*R. simus*) is as dolichocephalic as the Plistocene *R. antiquitatis*. The figure of the skull of the former, which the author has copied from some previous writer, is misleading; and if he had the opportunity of seeing the fine series of specimens in the British Museum, he would in all probability amend the statement.

Space prevents detailed notice of the interesting observations which the author gives on the evolution of the cheek-teeth in the group. It may, however, be observed that he is in accord with previous writers in regarding the white and woolly Rhinoceroses as presenting the culminating point of molar evolution among the typical Rhinoceroses; *Elasmotherium* representing a still more specialised offshoot by itself. At present we are left in some degree of doubt as to the author's views with regard to the generic or subgeneric divisions of the Plistocene and recent Rhinoceroses; but light will probably be thrown upon this point as the work proceeds. So far as they have been carried at present Prof. Osborn's labours afford, in the main, a distinct advance in our knowledge of a very interesting group, and the completion of his memoir will be anxiously awaited by all who have made the subject a special study. R. L.

THE BRITISH ASSOCIATION.

BRISTOL MEETING.

SECTION K (BOTANY).

OPENING ADDRESS BY PROF. F. O. BOWER, SC.D., F.R.S., PRESIDENT OF THE SECTION.[1]

II.

I. *Algae and Fungi.*

AT first sight those Algae and Phycomycetous Fungi which show a subdivision of the zygote appear to offer the key to the enigma of the first start of antithetic alternation, and such rudimentary fruit-bodies as those of *Oedogonium* and *Coleochaete* are frequently quoted as prototypes of sporogonia. My own position has been that they may be "accepted as suggestive of similar progress in the course of evolution of Vascular Plants." On the assumption that the zygote is equivalent in all cases—and this is itself a pure assumption—the fruit-body of such Algae or Fungi would be comparable to the sporophyte in higher forms; but it must be clearly remembered that it is not even then proved to be *homogenetic*. Dr. Scott has based a strong line of criticism of antithetic views upon these cases. He remarks: "The sudden appearance of something completely new in the life-history, as required by the antithetic theory, has, to my mind, a certain improbability. *Ex nihilo nihil fit.* We are not accustomed in natural history to see brand new structures appearing, like morphological Melchisedeks, without father or mother. Nature is conservative, and when a new organ is to be formed it is, as every one knows, almost always fashioned out of some pre-existing organ. Hence I feel a certain difficulty in accepting the doctrine of the appearance of an intercalated sporophyte by a kind of special creation."

In answer to this, I state that to me the zygote, from which our hypothesis starts, is not "nothing"; it is a cell with all the powers and possibilities of a complete cell. Vöchting, in his "Organbildung," has fairly concluded that "a living vegetative cell which is capable of growth has not a specific and unalterable function." I have myself demonstrated that cells typically sporogenous may develop as vegetative tissue, and conversely that tissues normally vegetative may on occasions become sporogenous. We may, therefore, say generally as regards the sporophyte, that "a living cell which is capable of growth has not a specific and unalterable function." This I conceive to have been the condition of the zygote, and of its early products.

I think that the words "intercalation" or "interpolation," as used by writers on antithetic alternation, have been quite misunderstood. I have contemplated no sudden development—indeed, on the first page of my "Studies" I have spoken of the sporophyte as "gradually" interpolated. Nor is the suggested development something "completely new," for I specially speak of elaboration of the zygote. This is the parent of these "morphological Melchisedeks"; and unless segmentation be held to be synonymous with "special creation," I confess I do not see where the initial difficulty arises. I agree that nature is conservative; what we contemplate is the fashioning of the sporophyte by a process of which the first step is segmentation, out of a pre-existing organ the zygote. Such simple segmentation is seen in the case of certain Algae and Fungi, and these may be taken as suggesting how the sporophyte of the Archegoniatae may have come to be initiated. But I am not aware of having ever suggested that these segmented zygotes of Algae are the homogenetic prototypes of the more elaborate sporophytes.

[1] Continued from p. 69.

Dr. Scott further states that "the reproductive cells produced by the ordinary plant of an *Oedogonium* are identical in development, structure, behaviour, and germination with those produced by the oospore." Prof. Marshall Ward, also speaking of *Œdogonium*, remarks "the attempt to get over this by terming asexual spores borne by the gametophyte *gonidia*, and reserving the term *spore* for bodies indistinguishable from these gonidia by any morphological or physiological character whatsoever, beyond their origin from a so-called sporophyte, carries its own refutation." Now, as a matter of fact, Pringsheim's description and figures of *Oedogonium* give scanty details; in most of the germinating zygotes the nuclei themselves are not clearly shown; much less the details of behaviour of those nuclei on germination. Klebahn has described the fusion of the sexual nuclei in *Oedogonium*, but I am not aware that he, or any one else, has yet made detailed observations on the nuclear condition of the zoospores, or the changes which take place in the germinating egg. Till this is done I submit that it is premature and undesirable to make such assertions as those of Dr. Scott and Prof. Ward. We now know that important nuclear changes do take place on the germination of the zygotes of certain Algae and Fungi. These changes are connected with a division of the nuclei into four, which is the number of the zoospores usually produced on germination in *Oedogonium*; the details may differ, but in the zygotes of *Closterium* and *Cosmarium*, and in the formation of the auxospores of *Rhopalodia*, Klebahn has demonstrated this division into four; also Chmielewsky has described a similar production of four nuclei in the germinating zygotes of *Spirogyra*. When it is further stated that in some of these cases there is good reason to think that a reduction of chromosomes is connected with the division into four, just as a reduction is now known to accompany the tetrad division in Archegoniate and Phanerogamic plants, it is plain that such cases as that of *Oedogonium* ought not to be assumed to support an homologous view without any fresh observation of the facts.

With the whole question of alternation, the nuclear details and differences in number of the chromosomes on division are now intimately bound up. Though the observations are still few, so far as they go they are consistent with the generalisation first stated by Overton, and elaborated by Strasburger as regards the Archegoniate and Phanerogamic plants. It has now been seen in cases drawn from various groups, that the cells of the gametophyte show a certain number (n) of chromosomes, while those of the sporophyte show on nuclear division double that number ($2n$) of chromosomes. Since Section K has had the advantage of a statement on this subject from Prof. Strasburger himself at Oxford, and as Dr. Scott also discussed the matter at Liverpool, I need not enlarge. I shall only remind you that Strasburger took up the position that the number of chromosomes which appears in each sexual nucleus is that original number which the ancestors possessed in a pre-sexual period; while the reduction of the double number which results from sexual fusion is, in his opinion, to be regarded as an atavistic process. As far as investigation has yet gone, I see nothing to prevent the acceptance of this as a provisional theory.

It is now well known, however, from the observations of Farmer and of Strasburger, that the nuclear conditions of *Fucus* are peculiar; that the reduction only takes place on the formation of the sexual organs themselves, and that the *Fucus* plant, like a sporophyte in the Archegoniate series, has the double number of chromosomes. At first sight this might appear to be a fatal difficulty, and Dr. Scott, attributing to the adherents of the antithetic theory views from which I personally dissent, has landed them in a seeming *reductio ad absurdum*. He himself does "not think we are as yet in a position to draw any morphological conclusions from these minute differences, interesting as they are." But we need not accept either of these extreme positions, if only a certain elasticity of theory be maintained, which should come naturally to adherents of polyphyletic development. I think the difficulty will chiefly be felt by those who, like some of the earlier writers on alternation, attempt to reduce all plants which show sexuality to one stiff scheme; this has been found to fail in the case of alternation, and a healthy recognition of various types of alternation has been the consequence. So in the matter of chromosomes, and of the position which the event of reduction holds in the life-cycle; difficulties such as this in *Fucus* may be anticipated, if we assume that all plants will conform to one plan. But Strasburger has not considered it necessary to cast aside the nuclear details as a basis for morphological conclusions, because all plants investigated do not fall in with a preconceived scheme. On grounds of comparison of behaviour of the nuclei before and after conjugation in *Closterium*, *Cosmarium*, *Spirogyra*, in certain Diatoms, and finally in *Actinophrys*, he has arrived at the conclusion "that a shifting (Verschiebung) of the time of division into four, together with reduction, is possible in the history of development of organisms." It will doubtless be necessary later to put a precise meaning upon the word "Verschiebung," and to define how far in given cases it is to be understood as an actual shifting of the event within one line of descent, how far it merely expresses an initial difference maintained, or it may be, extended, in different lines. Meanwhile, those who accept Prof. Strasburger's position will see that while in various evolutionary sequences the reduction may take place at different points in the cycle, still it may have settled down to a fixed and constant position in any one sequence; that I conceive to have been the case for the Archegoniate series. The validity of this conclusion does not seem to me to be affected by the diverse state of things seen in so far removed a sequence as that of the brown Algae.

Here a brief reference must be made to the very beautiful results of Wager on the changes in the zygote of *Cystopus candidus*, which have been verified and extended by Berlese. Wager states that in this fungus the process of fertilisation does not differ in any essential particular from the process as it takes place in Angiosperms. On the division of the fusion-nucleus of the zygote the number of the chromosomes present before division appears to be considerably in excess of the number observed in the nuclei of the oogonium. "By counting as carefully as possible 20 to 24 or even more appear to be present, and the impression is produced that the number is certainly much larger than that observed in the oogonium." Divisions of the nucleus then follow to form 4, 8, 16, and finally 32, in which condition a period of rest ensues; and finally, it appears that a division of each into four follows, to form the nuclei of four spores. Wager believes the reduction to take place at this last division, and Berlese has established a strong probability that such a reduction actually does take place. Plainly these observations are not final or conclusive, and even if they were, the strict homogeny of this fruit-body with a rudimentary sporophyte of a green plant would not be proved. It must, however, rank at least as an important parallel case, illustrating how the reduction may be effected in a distinct line of descent.

We see then that in green Algae such as *Oedogonium*, *Sphaeroplea*, and *Coleochaete*, certain divisions follow fertilisation, but we are not yet in possession of the nuclear details. I prefer, therefore, to suspend judgment as to the nature of those divisions; but in view of the peculiar behaviour already seen in other zygotes, it may be distinctly anticipated that some form of reduction will be demonstrated at that stage. If that be shown then we shall be right in recognising in these small cell-bodies the rudimentary correlative of a sporophyte—the sort of beginning from which a neutral generation may have sprung in land-living plants. We cannot go further than this as regards the green Algae until we are in possession of the facts. There is no greater desideratum in morphology at the present moment than a detailed knowledge of the germination of zygotes such as that of *Oedogonium*.

Here I may remark that the admirable observations of Prof. Klebs, whom the Section will welcome as a distinguished guest, do not appear to me to touch this question. His very varied and convincing experiments show in a number of Algae and Fungi that, as regards the succession of vegetative and sexual modes of propagation, the experimenter has a very complete control. I do not find, however, any observations of his which touch the behaviour of germinating zygotes of green Algae as regards details of segmentation. I do not mention this as in the least impairing the brilliancy of Prof. Klebs's work, but because Prof. Ward has brought Klebs's results to bear upon the discussion on antithetic alternation in a manner which I do not think that the facts will support.

II. *Bryophyta*.

Turning now to the Bryophytes, these plants stand at the moment in a somewhat discredited position. We have been warned by Dr. Scott that "there is no reason to believe that the Bryophyta, as we know them, were the percursors of the Vascular Cryptogams at all," and that "there is no appreciable resemblance between the fruit of any of the Bryophyta and the plant of any Vascular Cryptogam," and the suggestion has been

thrown out afresh that they may really be "degenerate descendants of higher forms."

In view of statements such as these it may be well to examine the Bryophyta quite separately, without reference to Vascular Plants at all, and see what are their main bearings on theories of alternation. And if the Bryophytes were the only Archegoniate Plants in the world, I think the case for their origin by a progressive antithetic alternation would be an uncommonly strong one; the points which are especially noteworthy are: (1) The readiness with which they may be arranged in natural sequences which illustrate increasing vegetative complexity of the sporophyte as a consequence of progressive sterilisation; (2) The nuclear details, which are as yet known, however, in only few cases; (3) The constancy of the two alternating phases, the relations of which are very seldom disturbed by apospory, and never, to my knowledge, by apogamy.

The first of these matters has been dealt with at length in my "Studies." It is, of course, possible for any one to read such sequences as are there mentioned in reverse order, and to uphold a theory of simplification; but this must be shown to be in accordance with probability. Now it appears to me that the general probability in the case of the Bryophytes is against simplification, for the larger the number of spores which can be matured the greater the probability of survival; even in cases where, as in *Buxbaumia* and *Diphyscium*, there is an exiguous, and probably reduced Moss-plant, the sporogonium is not of a reduced type, but, on the contrary, unusually large. It seems to my mind much more probable that the Bryophytes as a whole illustrate a course of progressive complexity. A comparison of anatomical details frequently suggests a progressive sterilisation, a process which we see demonstrated both in Pteridophytes and Phanerogams, where actual conversion of potentially sporogenous tissue into temporary or permanent vegetative tissue does occur. When it is added that the nuclear evidence, scanty though it still is, shows the sporophyte with a double number of chromosomes, and the reduction taking place on the tetrad division of the spores, the comparison with the segmented zygotes of Algae and Fungi above mentioned seems inevitable. The position of those who hold views of antithetic alternation will, therefore, be that the simple sporogonium was produced as a post sexual growth. The starting-point was probably some such multicellular body as we see nowadays in certain Algae and Fungi resulting from division of the zygote, but not necessarily homogenetic with any such body that we know now living. The land habit imposed a restriction on fertilisation, and an alternative method of increase in numbers was an advantage. The multicellular body resulting from division of the zygote provided the means for this; the cells developed separately as dry, dusty spores. As the number of divisions increased, the powers of the plant to nourish, protect and disseminate the spores became the measure of the number produced. Hence followed the elaboration of the nourishing and disseminating mechanism, which has involved a diverting of some cells from their first office of spore-production, the start being, perhaps, made in a manner similar to the formation of the peridium in the Uredineæ. To my mind—taking the Bryophyta alone—there is an inherent probability in all this, which far counterbalances any of the obstacles which have been raised against it.

The greatest obstacle is the fact of apospory in Mosses. This departure from the usual alternation will be more generally discussed in relation to the Ferns, where it is more frequent. Besides its being artificially induced in Mosses by special treatment, it appears also to have been noted by Ugo Brizi in nature, in the case of atrophied capsules of *Funaria*, which had buried themselves in the soil. The essential point is the production of the sexual generation by direct vegetative growth from the neutral. This would appear to involve a reduction of chromosomes, but Pringsheim's drawings show nothing analogous to the usual process of tetrad division to form the spores; the reduction, if it occurs, must be effected in some other way.

A theoretical suggestion on this point will be made later. Meanwhile let us estimate its probable importance as regards the Bryophyta. It cannot fail to strike the observer how uniform is the alternation in these plants; there are, I believe, no recorded cases of deviation from the normal alternation in Liverworts. I know of only a single case of apospory among Mosses taken in the open, and then in atrophied capsules; apospory, when induced, follows such extreme treatment as chopping the sporogonium into pieces. And it is not as if the Mosses and Liverworts had escaped detailed observation; hardly any group of plants had been more carefully examined by competent observers. Deviations from strict alternation then are rare, and appear under physiological stress. This great group, which includes the simplest sporophytes among Archegoniate plants, is also singularly constant in its alternation. I think this is to be connected with the permanently dependent condition of the sporophyte; its equable physiological condition, nursed and protected by the Moss plant, finds its morphological expression in its comparative uniformity. Conversely the independent position of the sporophyte in Ferns, and its exposure to varied conditions may have elicited more freely in them unusual developments.

III. *Abnormalities.*

And now I may pass to my third point, and discuss more generally the argument from abnormalities. I have no wish to prejudge the question by the use of this term as applied to apogamy and apospory, or in any way to detract from their morphological importance—I merely intend to express that they are departures from that order of events which is the most frequent in Archegoniate plants at large, and I particularly wish to point out that while such irregular developments are now shown to be frequent in Ferns, they are exceedingly rare in Bryophytes, and are not, I believe, hitherto recorded for Lycopodineae or Equisetineae.

While direct vegetative transitions from one generation to the other may appear as a *primâ facie* support of an homologous origin of the two generations, I must protest against their being used, as they have been, as evidence against an antithetic view. It has been said that the facility with which these transitions from one generation to another in Ferns take place "shows that there is no such hard and fast distinction between the generations as the antithetic theory would appear to demand." Why should it demand a hard and fast distinction? For my own part, I had already described apogamy and apospory as occurring in the same individual before I wrote on alternation. The presumption seems to be that a distinct course of evolution must have imposed "hard and fast" limits upon the potentialities of the parts evolved. But we ought to remember how the root, whether in Phanerogams or Ferns, has doubtless had a long course of evolution as a member distinct from the shoot; and yet we see it bearing adventitious buds upon it, as in the Rosaceae, Poplar or Elm; or even transformed at its apex into a shoot, as in *Platycerium* or *Anthurium*. Such cases as these, though not exact parallels, should suffice to show that hard and fast lines are not to be anticipated as a consequence of a distinct course of evolution.

There is another kindred, though almost converse, proposition which has been advanced by Pringsheim. He made his experiments on Moss fruits, "in the hope that he would succeed in producing protonema from the subdivided seta of the Mosses, and thus prove the morphological agreement of seta and Moss-stem." The point here appears to be that parts which are capable of producing similar growths are in "morphological agreement." I cannot assent to this proposition. In the case of the roots above quoted, the production of buds upon them, or the conversion of their apices into shoots, does not prove their "morphological agreement" with shoots upon which such developments are common.

By those who use such arguments it is to be borne in mind that the two generations, however distinct in their evolution, are still merely stages in the life-history of one and the same organism. The hereditary qualities of the race as a whole must be transmitted through the successive generations. It may be a question how far, and under what conditions, its various potentialities come into evidence, as, for instance, in the formation of an apogamous sporophyte, or of an aposporous protonema; but that some such potentialities are there is in no way inconsistent with the antithetic theory.

I have above pointed out how morphology has recently passed to an experimental stage, and I am glad to say that by means of the cultures of Dr. Lang and others we are beginning to gain an insight into the circumstances which lead to these phenomena. In certain Ferns direct apogamy occurs: that is, "the immediate production of vegetative buds by prothalli which are usually incapable of being fertilised"; the origin of this is still obscure. But apogamy may also be induced in various other species. Dr. Lang states that "the causes which appeared to induce apogamy in these prothalli were, the prevention of contact with fluid water, which rendered fertilisation impossible, and

the exposure to direct sunlight. Possibly the temperature had some effect." It is further to be noted that in every case of induced apogamy "normal embryos were produced when conditions permitted fertilisation." Now the conditions of prevention of fertilisation, exposure to light, and possibly also a high temperature, all lead to a plethoric state, which we may thus recognise as a precursor of induced apogamy, possibly also of apogamy at large.

On the other hand, the circumstances which precede or accompany apospory are commonly those of deficient nutrition. In the case of Ugo Brizi's *Funaria*, it is mentioned that the capsules were atrophied and buried in the soil, where they could not obtain nourishment by their own assimilation. In the induced apospory of Stahl and Pringsheim the growths appear upon parts of the chopped up seta, isolated from their usual sources of supply. Among Ferns, the conditions of nutrition which precede apospory have not been noted in all cases; but the following facts are interesting. *Athyrium Filix-foemina* var. *clarissima* is a pale chlorotic Fern with exiguous leafage, while the more or less complete arrest of the sporangia is a concomitant of apospory. In *Polystichum angulare* var. *pulcherrimum* there is no obvious disturbance of the vegetative organs, but I have specially noted the sporal arrest, which, in the specimens examined by me, appeared to be complete. This is, then, a concomitant of apospory, though it may be uncertain how far there is a casual connection. In the case of apospory in *Pteris aquilina*, reported by Farlow, there is an irregular diminution of leaf-area in the pinnules which show apospory; this is accompanied by various stages of abortion of the sporangia, though some fully-matured spores were found. Here, as also in *Polystichum angulare*, the tips are specially affected. Farlow remarks, "the sporangia became more and more irregular the nearer they were to the tip." In the case of *Scolopendrium vulgare*, the plants which showed apospory at so peculiarly early a stage had been raised by Mr. Lowe from prothalli which had been repeatedly divided, a process calculated to affect the physiological condition. The aposporous plants of *Trichomanes alatum*, *pyxidiferum*, and *Kaulfussii*, were all cultivated under artificial conditions, and are characteristically shade-loving plants, a habit which must affect their nutrition. Perhaps the most interesting case, however, is that described by Atkinson in *Onoclea*. In plants from which, by removal of the foliage leaves, the sporophylls had been induced to change their character and develop as foliage leaves, the sori were arrested. "When the leaf has lost so much of its reproductive function that the sporangia are becoming rare or rudimentary in the sorus, apospory frequently occurs, and the placenta develops among the rudimentary sporangia prothalloid growths." Here is, again, a case of deficient nutrition; the assimilating leaves, after formation, but before they could have carried their functions far, were removed. The plant makes an effort to supply their place at the expense of spore-production; arrest of sori and sporangia is the result, accompanied by cases of the direct vegetative transition to the prothallus. From these examples we see that deficient, or, at least, disturbed nutrition is frequently, perhaps always, a concomitant of apospory. Thus there is some countenance for the view that apospory and apogamy follow on converse conditions of nutrition.

We may next inquire how these converse conditions may lead to the changes in question; and especially the state of the nuclei ought to be considered. Owing to practical difficulties of observation the behaviour of the nuclei in apogamy and apospory has not been directly followed. But if the nuclear difference between the two generations be as it is believed, nuclear changes will be closely connected with these vegetative transitions. What could appear more natural than that apogamy, which presumably involves a doubling of the chromosomes, should follow a condition of plethora, and that apospory, which presumably involves a halving of the chromosomes, should follow deficient nutrition?

One further fact in either case appears to me to be specially noteworthy, that the changes are not confined to a single cell. The directly apogamous bud of *Nephrodium Filix mas* may perhaps be referable to a single cell, but Dr. Lang shows by numerous examples that the transition from characteristic tissue of the gametophyte to that of the sporophyte may arise at various points, and involve considerable tracts of tissue. Similarly I have shown in the case of apospory that the change may affect not one cell only, but cell-groups at various and distinct points on the same individual. It would seem that there is a widespread disposition of the tissues to undergo the change.

For my own part, I think the usual attitude on the chromosome question has been too absolute and arithmetical. Evidence is accumulating from various sources that the usual numbers are not strictly maintained; it is known that in vegetative cells there are often considerable differences of the number of chromosomes from those in the sexual cells of the same plant, while observers have noted the irregularities in the divisions of the pollen mother-cells in such plants as *Hemerocallis* and *Tradescantia*. If there be any causal connection between the number of chromosomes and the morphological character of the sporophyte and gametophyte, irregularities such as these at least countenance the idea of nuclear instability being possible; it will be a question for special treatment and investigation how far nuclear instability is connected with disturbed nutrition. But into the mechanism of the presumable nuclear change, and the question whether it be sudden or gradual, we cannot enter with any more than a speculative interest, in the absence of direct observations. Whatever the nuclear details may be, I regard it as a matter of very great importance to recognise that special conditions of nutrition commonly accompany, if indeed they do not actually determine, those changes which we term apospory and apogamy. But the story of the past is not simply a matter of conditions of nutrition, as we see them now influencing Archegoniate plants in their present highly specialised state. The real question is a purely historical one, How *did* the present state of things come about?

(*To be continued.*)

THE TEACHING OF SCIENCE IN ELEMENTARY SCHOOLS.[1]

YOUR Committee are able to report that the quantity, if not the quality, of the teaching of science subjects in elementary schools has made progress during the past year. The following table, made up from the return issued by the Education Department, gives the figures for the scientific class subjects as compared with English. In the report for last year it was mentioned that the number of school departments taking object lessons would greatly increase, as the Government code of regulations announced that they would become obligatory in the three lower standards on and after September 1, 1896. We now see the result, so far as the schools are concerned whose school year ended between August 31, 1896, and August 31, 1897, but the full effect cannot appear until the next year's return, the whole of which will be in the obligatory period.

Class Subjects — Departments	1890–91	1891–92	1892–93	1893–94	1894–95	1895–96	1896–97
English	[illegible]	18,175	17,394	17,032	[illegible]	[illegible]	[illegible]
Geography	12,806	13,485	14,256	[illegible]	15,702	[illegible]	[illegible]
Elementary Science	173	788	1,073	1,215	[illegible]	[illegible]	[illegible]
Object Lessons ...	—	—	—	—	—	[illegible]	[illegible]

The number of departments in "schools for older scholars" for the year 1896–97 was 23,080, all but 10 of which took one or more class subjects. But history was taken in 5133 departments, and needlework (as a class subject for girls) in 7397 departments, and sundry minor subjects in 1056, making, with the other four subjects of the table, a total of 55,456. This shows an average of more than 2½ class subjects to each department; but it must be borne in mind that the same subject is not always taken in all the standards, in which case three class subjects will appear in the return.

It was remarked in the last report that "the increased teaching of scientific specific subjects in the higher standards is the natural consequence of the greater attention paid to natural science in the lower part of the schools." The following table shows the correctness of this inference:

[1] Report of the Committee consisting of Dr. J. H. Gladstone (Chairman), Prof. H. E. Armstrong (Secretary), Prof. W. R. Dunstan, Mr. George Gladstone, Sir John Lubbock, Sir Philip Magnus, Sir H. E. Roscoe and Prof. S. P. Thompson. (Read before Section L of the British Association at the Bristol Meeting.

Specific Subjects—Children	1891–92	1892–93	1893–94	1894–95	1895–96	1896–97
Algebra	28,542	31,487	33,612	38,237	41,846	47,225
Euclid	927	1,279	1,399	1,468	1,584	2,059
Mensuration...	2,802	3,762	4,018	5,614	6,859	8,619
Mechanics	18,000	20,023	21,532	23,806	24,956	26,110
Animal Physiology	13,622	14,060	15,271	17,003	18,284	19,989
Botany	1,845	1,968	2,052	2,483	2,996	3,377
Principles of Agriculture ...	1,085	909	1,231	1,196	1,059	825
Chemistry	1,935	2,387	3,043	3,850	4,822	5,545
Sound, Light, and Heat ...	1,163	1,168	1,175	914	937	1,040
Magnetism and Electricity	2,338	2,181	3,040	3,198	3,168	3,431
Domestic Economy	26,447	29,210	32,922	36,239	39,794	45,869
Total	98,706	108,434	119,295	134,008	146,305	164,089

It appears that the mathematical subjects still command the most favour on the part of the teachers, algebra having taken a very remarkable lead. All the physical sciences have increased even more than might have been expected from the increase of scholars. The principles of agriculture is the only subject that shows an actual decrease.

Estimating the number of scholars in Standards V., VI., and VII. at 615,000, the percentage of the number examined in these specific subjects, as compared with the number of children qualified to take them, is 26·6; but it should be remembered that many of the children take more than one subject for examination. The following table gives the percentage for each year since 1882, and shows that science is gradually recovering from the great depression of about eight years ago:—

	Per cent.		Per cent.
1882–83	29·0	1890–91	20·2
1883–84	26·0	1891–92	19·7
1884–85	22 6	1892–93	20·2
1885–86	19·9	1893–94	20 9
1886–87	18·1	1894–95	22·7
1887–88	16·9	1895–96	24·2
1888–89	17·0	1896–97	26 6
1889–90	18·4		

The Returns of the Education Department here given refer to the whole of England and Wales, and are for the school years ending with August 31. The statistics of the London School Board are brought up to the year ending with Lady Day, 1898. They also illustrate the great advance that has been made in the teaching of elementary science as a class subject, and they give the number of children as well as the number of departments.

Years	Departments	Children
1890–91	11	2,293
1891–92	113	26,674
1892–93	156	40,208
1893–94	183	49,367
1894–95	208	52,982
1895–96	246	62,494
1896–97	364	86,638
1897–98	322	70,626

The last year shows an apparent falling-off in the teaching of this subject, but, as has been mentioned above, the Government having made the giving of object lessons obligatory in the lower standards, 442 departments, with 75,993 children, have already adopted them. This has caused a reduction in the teaching of "Elementary Science" under that name; but, taking the two subjects together, this must be regarded as a very considerable gain.

The Education Department continues to meet the objection against the limitation under the Code by which only two class subjects are allowed to be taught, by adding combined courses of study. This year a new course of this character has been introduced into Schedule II, described as "Elementary Science and Geography Combined." And as, under the present regulations, one of the class subjects must be such as can be taught by means of object lessons in the lower standards, some such subject as the combined one above mentioned must be taken. A copy of the scheme is given in the Appendix, by which it will be seen in the lower standards the phenomena of the land and water are to be illustrated experimentally as an introduction to geographical science.

A similar principle has been adopted in respect of the specific subjects. Hitherto chemistry has formed a course of itself, and physics has been divided into two separate courses, the one dealing with sound, light, and heat, and the other with magnetism and electricity; but they formed only three out of the nineteen subjects from which choice could be made. A separate course of elementary physics and chemistry combined has now been introduced, which is set out in the Appendix, and which is admirably adapted for experimental investigation at the hands of the students themselves.

The work under the Evening Continuation Schools Code continues to progress, as will be seen from the following table:—

Science Subjects	Units for Payment							
	England and Wales				London School Board			
	1893–4	1894–5	1895–6	1896–7	1893–4	1894–5	1895–6	1896–7
Euclid	595	1,086	1,648	2.270	10	29	7	—
Algebra	3,940	6,657	10,374	14,260	316	302	535	714
Mensuration ...	14,521	32,931	41,772	50,748	279	374	452	36[illegible]
Elementary Physiography	2,554	4,045	6,590	6.325	37	9	5	—
Elementary Physics and Chemistry ...	6,500	7,850	6,749	5,183	79	200	152	12[illegible]
Science of Common Things	6,223	10,350	12,906	18,293	231	262	468	55[illegible]
Chemistry ...	3,484	7,814	8,222	9 641	212	455	404	48[illegible]
Mechanics ..	841	1,148	1,458	2,196	230	197	209	12[illegible]
Sound, Light, and Heat ...	500	1,046	861	1.156	—	15	11	[illegible]

Agriculture ...	3,579	4,991	4,694	4.061	—	—	—	—
Horticulture ..	438	1,140	1,812	1,911	—	—	—	—
Navigation ...	42	69	142	99	—	—	--	—
Totals ...	51,607	92,520	111,031	134,260	2,152	2,778	3,179	3,410

It is again evident that the mathematical subjects are rapidly increasing in favour, and that agriculture is decreasing. It will be noticed with satisfaction that the science of common things is receiving greatly increased attention, but it is a matter of regret that there is a decrease in the time given to elementary physiography, and still more so in the case of elementary physics and chemistry. Agriculture would become a more valuable and probably a more popular subject of study if a really good practical course were devised.

An important change has been taking place in Scotland. The Code of the Scotch Education Department now admits of the possibility of gaining the full class grant, although only two subjects are taken. As one of these must be English, and in the higher standards provision must be made for history or geography or both, the teaching of science as a class subject has been greatly reduced during the last two years. But a new article in the Code for 1895 offers a special grant of a shilling on the average attendance of boys who are satisfactorily taught "elementary science"; and this has far more than made up the deficiency. In fact the aggregate total of children learning elementary science in the Scotch schools has risen from 34,151 in 1894-95 to 85,671 and 133,855 respectively in the two succeeding years.

Your Committee have frequently referred to the anomaly that pupil teachers are not obliged to receive any instruction in natural science, although they may have to give instruction in such subjects, either specifically or in the form of object lessons; indeed, if they should be in charge of a class of the three lower standards it would be obligatory upon them to give such object lessons. A Departmental Committee, consisting of the Rev. T W. Sharpe, Her Majesty's Chief Inspector of Schools, as Chairman, and several Inspectors and Principals of Training Colleges and Pupil-teacher Centres, have reported upon the pupil-teacher system. They recommend that the age for entering as pupil teachers should be raised, and that the interval between the elementary school and their apprenticeship should be passed at a secondary school. This would by no means ensure that the young people would receive any instruction in science during that period of their career. No alteration is proposed

in the optional science course prescribed by the Code of the Education Department, except that the Queen's Scholarship examination is to be limited to the elementary stage of physiography prescribed in the syllabus of the Science and Art Department. With regard to the college course the recommendation is singularly weak, science being placed as an optional subject, without any definite course of study prescribed. For the first two years it is laid down that of the optional subjects not more than two must be taken out of a list of four or six respectively, some of which from their very nature are almost sure to be taken in preference.

An important letter has been addressed to the Right Hon. Sir John Gorst by Sir Philip Magnus, the Chairman of the Joint Scholarship Board, in conjunction with the Chairmen of its four educational committees. They point out the necessity of securing the proper training of those who will be teachers of scientific subjects, and that the instruction of pupil teachers in science is now often carried on, under great pressure, by a system of cram, and even by persons who have not themselves any satisfactory knowledge of modern scientific methods. They suggest as a remedy that the first part only of the elementary stage, physiography, be compulsory; that the teaching of this subject be recognised only where it is given with proper accessories, all pupils performing the experiments in a series of at least twenty-four lessons of two hours' duration; and that inspectors should be required particularly to report whether proper apparatus and accessories are provided.

In last year's report your Committee referred to what Mr. Heller was doing in respect of the teaching of science in the schools of the London School Board. He has since obtained a better appointment at Birmingham, but the syllabus of lessons which he prepared is still employed in the schools. This of course requires that the masters and mistresses should be qualified for carrying it out, and for this purpose classes of twenty-four hours are conducted for their benefit by the science demonstrators. These gentlemen have lately agreed upon two separate syllabuses for masters and mistresses, which follow in general the scheme they are expected to teach to their scholars. The classes of a similar kind that have been carried on hitherto have been appreciated by the teachers, and the Board are increasing their laboratory and other accommodation for the purpose. It is recognised that it will be necessary to continue these teachers' courses for some years, in order to overcome the difficulty which now exists in consequence of the general want of practical experiment in such instruction in science as has been given in the course of training of most class teachers.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The 194th meeting of the Junior Scientific Club was held in the Physiological Lecture Room of the Museum at 8 p.m. on Wednesday, November 16. After the election of new members, Mr. A. F. Walden (New College) brought forward his motion respecting the appointment of a Committee to act with the Treasurer of the Robert Boyle Lecture Fund. The motion was carried, and the Club elected Mr. A. E. Boycott (Oriel) and Mr. A. S. Elford (St. John's) to serve on the Committee. Mr. A. D. Darbishire (Balliol) read a paper on natural selection among Lepidoptera. His remarks were illustrated by several cases of butterflies. Mr. J. E. Marsh (Balliol) followed with a paper on the constitution of camphor, in which he attempted to survey all the recent work on the subject.

MR. ERNEST WILSON has been appointed professor of electrical engineering at King's College, London, in succession to the late Dr. John Hopkinson.

DR. GIUSEPPE SANARELLI, of the Uruguayan Medical School and Director of the Hygienic Institute at Montevideo, whose discovery of the microbe of yellow fever has brought him much distinction, has, the *Lancet* states, been offered by Dr. Baccelli (Minister of Public Instruction) the chair of Hygiene in the University of Bologna, left vacant by Prof. Roncati.

THE two first formal steps towards the establishment of a Midland University, to be called the University of Birmingham, were taken on Friday last, at a meeting of the Court of Governors of Mason University College. In reference to the scheme, the Management Committee reported that, in their opinion, the University to be established in Birmingham should be a teaching University, as distinguished from a University which only examines students for degrees. The University should therefore have the control and direction of all the teaching as well as the examining of students. With this end in view the Committee recommend that, if an agreement can be made with the governors of Mason University College, the University should be allowed to absorb the college. In this case the college would cease to exist as a separate institution, and its endowments, buildings, equipment, and staff would be transferred to the University. The Committee have had under consideration the financial position of the University. They are of opinion that, in order to completely carry out the above scheme, an endowment of not less than 200,000*l*. is required beyond that already held by Mason University College. Such an endowment would just double the present endowment of the college. The Committee expressed their opinion that every effort should be used to at once increase the endowment fund in order that an endowment of not less than 200,000*l*. may be obtained to enable the University to start under favourable conditions.

Mr. Chamberlain moved the two resolutions, one recommending that steps be taken to absorb and include Mason College in the new University; and the second, authorising the Council of Mason College to take the necessary measures to obtain a Royal Charter for the establishment of the University. In presenting these resolutions Mr. Chamberlain remarked: "I think our ideal may be stated in a few words to be the creation in Birmingham of a great centre of universal learning, of an institution which should provide for the intellectual cultivation of mind in the broadest possible sense, and which shall maintain for ever in the city the highest standard of intellectual eminence. We desire that in this school all acquired knowledge should be taught and explained, and we further desire that knowledge should be advanced by original research, and by the willing co-operation of those who are engaged as professors and teachers. The enormous development of science requires undoubtedly an extended application of the means of instruction. Of course, there is special reason why science should take a very prominent place in connection with a University which is situated in the centre of a manufacturing and commercial district, and it would, in my opinion, be pedantry were we to pretend that we did not attach the highest importance to this branch of our work, and did not intend that it should be distinctly carried out and should give to the University a special position of its own."

REFERRING to the address delivered by Mr. Chamberlain on the subject of a University of Birmingham, and referred to above, the *Times* remarked on Monday: "Those who carefully study German commercial methods are well aware that the chief cause of German success at the present time is the German manufacturers' respect for science. There is at the present moment at Düsseldorf a chemical company which employs thirty-three trained chemists, picked University men, who are paid good salaries with a share of the profits due to any invention which they may make; this company pays very high dividends, and its business has increased by leaps and bounds. It would be interesting, but not encouraging, to learn what has been the parallel history of the chemical works on the Tyne. This points to one way in which a Birmingham University, properly equipped, worked and encouraged, may affect the commercial prosperity of the city."

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No 10.—Gravitational constant and mean density of the earth, by F. Richarz and O. Krigar-Menzel. The gravitational constant, *i.e.* the constant which has to be inserted in the equation for determining the attraction from the product of the masses and the inverse square of their distance apart, when C.G.S. units are chosen, was found by the method of weighing a mass at two different altitudes above the earth's surface. The result arrived at was $6{\cdot}685 \times 10^{-8}$. The value for the mean density of the earth was $5{\cdot}505 \pm 0{\cdot}009$.—Surface tension in narrow capillary tubes, by P. Volkmann. When measurements are made on freshly-drawn capillary tubes, the results are well in accordance with the known laws, whatever the substance and diameter of the tubes. In old and wide tubes the surface tension is higher

by 0·02 mgr./mm., probably owing to the absence of solubility of the substance of the older specimens of glass.—A method for determining the thermal conductivity of solids, by F. A. Schulze. A rod of the material examined is at the temperature of the room. At a short distance from one end a thermo-couple is inserted. From a given instant, the end surface is exposed to a stream of water at a different temperature. Knowing the specific heat of the body, the author works out in detail an equation for finding the thermal conductivity, and illustrates it by examples which show a maximum error of 4 per cent.—Specific heats of metals at low temperatures, by U. Behn. If the decrease of the specific heat with the temperature is represented graphically, it appears probable that all the curves intersect at the temperature of absolute zero. At that temperature it is also possible that the specific heats themselves are zero. In any case, Dulong and Petit's law does not hold for low temperatures.—Coherers, by E. Aschkinass. The theory of the coherer according to which the decrease of resistance is accounted for by sparks which weld the particles temporarily together, does not suffice for the case of peroxide of lead, where the resistance increases under the influence of electric waves. The coherer action pure and simple is only observed under feeble electric radiation. When the latter is strong, disturbing influences supervene. Electrical and thermal measurements made on discharge tubes, by E. Wiedemann and G. C. Schmidt. When the appearance of discharge tubes is similar, whether they are fed by an influence machine or a continuous current, it is safe to assume that the potential gradients are the same. The values of the potential gradient as derived from probes and from calorimetric measurements respectively are the same, but the latter method is more suitable when the discharge is discontinuous.

Bollettino della Società Seismologica Italiana, vol. iv., 1898, Nos. 2, 3.—Echo in Europe of the Indian earthquake of June 12, 1897, by G. Agamennone. Seismoscope with multiple effect, by A. Cancani. The earthquake of Grandson [February 22, 1898], by F. A. Forel, a paper (in French) describing a series of short waves, about half a metre in height, which were observed on the lake of Neuchâtel at the time of this earthquake.—On the various systems of registration in seismology, by A. Cancani.—On the Rieti earthquake of June 28, 1898, by G. Brucchietti. An account of the damage caused by this earthquake at Rieti and elsewhere.—Notices of earthquakes recorded in Italy (July 27–September 17, 1897), by G. Agamennone, the most important being the earthquakes of Japan on August 4–5, Turkestan on August 15 and September 17, and Tuscany on September 6, and earthquakes of unknown, but distant, origin on August 6, 13, 16, 20 and 26.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, November 2.—Mr. G. H. Verrall, Vice-President, in the chair.—Mr. Merrifield exhibited some *M. aurinia* from Touraine forced and cooled as pupae, the latter being much the darker and more strongly marked, some *E. cardamines* from Sussex, those cooled having the apices of the wings darker and the discal spots smaller than those which have been forced, and some *C. edusa* from eggs laid by two normal females taken in Savoy, two out of the five reared being of the var. *helice*; the marginal border of one male, which had been forced, was very pale and much suffused with long yellow scales. He also showed four *P. machaon*; two of them, forced as pupae, had their dark parts very pale and their tails long and slender, the two which had been cooled having the dark parts much extended in area and darkened in hue, their tails being short and broad. These results, which were to be obtained with winter as well as summer pupae, corresponded with those previously obtained by Dr. Standfuss.—Mr. J. J. Walker exhibited two winter nests of *Porthesia chrysorrhoea* from the Isle of Sheppey, where the species had lately become very common.—Dr. Mason exhibited a Buprestid larva found among Baltic timber at Burton-on-Trent. This had been among wood in a box since the beginning of July last, and there was scarcely a trace of frass. Marsham had recorded the escape of a larva of *Buprestis splendens* from the wood of a desk in the Guildhall, which had stood there for more than twenty years. It is probable that the growth is extraordinarily slow, and consequently that the larva can maintain life for very long periods in most unfavourable conditions.—Mr. Blandford called attention to similar cases which he had brought before the Society. It appeared likely to him, from what was known about such insects as *Callidium variabile*, which was occasionally bred from dry wood at long intervals, that these species were not abnormally slow-growing under normal conditions, but became so in dry timber, in which they probably sustained life with difficulty, especially when the outside of the wood was varnished.—Mr. Waterhouse exhibited for Mr. G. W. Kirkaldy living examples in various stages of a *Caryoborus* in nuts of *Attalea funifera* from Brazil. Elditt had described the attacks of an allied species upon the seeds of *Cassia fistula*.—Mr. Tutt exhibited for Dr. Chapman a series of Swiss examples of *Zygaena exulans*, and discussed the differences between them and the Scotch form.—Papers were communicated by Mr. W. F. H. Blandford on some Oriental Scolytidæ of economic importance with descriptions of five new species, and by Mr. van der Wulp (through Colonel Yerbury) on Asilidae from Aden and its neighbourhood.

Linnean Society, November 3. Dr. A. Günther, F.R.S., President, in the chair.—The President exhibited an abnormal twin tusk of an adult Indian elephant, and made the following remarks. The tusk occupied the right jaw of the animal. The two teeth were developed from separate papillae and remained perfectly separate, without any connecting ossification, although they grew side by side from the same socket, the uneven surface of one closely fitting into that of the other. He was inclined to look upon the smaller tooth as a persistent milk-tooth, which, not being shed, continued to grow from its original papilla; but Mr. Charles Tomes, F.R.S., considered it a case of duplication, such as is sometimes found in man and other mammals, in which the development of two separate papillae gives rise to a twin tooth of the permanent dentition. No such case seems to have been previously observed in the elephant.—Prof. G. B. Howes, F.R.S., exhibited some young and six living eggs of the New Zealand lizard *Sphenodon* (*Hatteria*), received from Prof. A. Dendy, of Christchurch, N.Z., part of a full series which had furnished that gentleman with material for a monograph on the general development of the animal, now in course of publication. Briefly referring to the previous attempt of Parker and Thomas to secure material for the study of this subject, he said that the palaeontological discoveries of Credner justified us in regarding the Rhyncocephalia as the most central among terrestrial vertebrata. He remarked that the specimens had been sent him for the express purpose of working out the development of the skeleton. Recapitulating the more salient discoveries recently announced by Prof. Dendy in his preliminary paper in the *Proc. Royal Soc.* and elsewhere he said, in comment upon them, that the plugging of the nostrils by cellular tissue during development is a phenomenon already described by the late T. J. Parker in *Apteryx*, and that it appeared to him akin to that of the occlusion of the oesophagus of the vertebrate embryo first described by Balfour, which De Meuron had sought to associate with the metamorphosis of the branchial diverticula. He pointed out that Dendy's discovery of a third pair of incisors was confirmatory for the upper jaw of the conclusions of the late Dr. G. Baur, and remarked that he had received a letter from Prof. Dendy, dated September 12, stating that he and his colleagues at the Antipodes had secured a Government order protecting the eggs as well as the young of *Hatteria*.—Mr. A. F. Crossman exhibited some photographs illustrating the case of a chicken hatched and reared by a common buzzard. The buzzard had laid an egg in captivity, and manifesting a desire to incubate, a hen's egg was substituted, which in due course was hatched and the chicken reared, the foster-parent feeding it upon morsels of flesh. It thus appeared that in a conflict of instinct, under altered conditions of life, the maternal instinct had proved stronger than the natural impulse to kill and devour weaker prey. Mr. J. E. Harting remarked that the case was not an isolated one, instances of buzzards rearing chickens having been previously recorded (*Zool.*, 1881, p. 103), as well as several cases of eagles hatching goose-eggs and rearing the goslings (NATURE, April 1879, and *Field*, February 1896). Messrs. H. and J. Groves exhibited specimens of *Nitella hyalina*, Agardh, a new British plant, and made some remarks on its affinities and distribution. Mr. W. Carruthers, F.R.S., and the President made some observations by way of comment.—Prof. H. Marshall Ward, F.R.S., read a joint paper by Miss Dale (Pfeiffer student of Girton College) and himself on *Craterostigma pumilum* (Hochst.), a rare plant

which had been brought from Somaliland by Mrs. Lort Phillips. As it had flowered in the Cambridge Botanic Garden during the past summer, and ripe capsules and seeds were obtained, a complete description was possible.—The Rev. T. R. Stebbing, F.R.S., read a paper on "Amphipoda from the Copenhagen Museum and other Sources," in continuation of a former memoir on this subject (*Trans.* Linn. Soc., *Zool.*, vol. vii. part 2). Several new species and a few new genera were described.

Royal Microscopical Society, October 19.—Mr. E. M. Nelson, President, in the chair.—The President referred to a microscope made by Reichert, and exhibited by Messrs. Baker. It was designed for examining opaque objects; a reflector was fitted in the tube of the microscope, which threw the light down upon the object through the objective. This was an old idea revived, but in its present form it was said to be very useful in steel works for examination of fractures of the metal.—Mr. C. Beck exhibited four new students' microscopes, mounted upon true tripod stands.—Messrs. Watson and Sons exhibited another microscope, named the "Fram," specially designed for students' use.—The President exhibited an old microscope by John Cuff, of Fleet Street, date about 1760; and also an old French microscope, date about 1765. He then described some micro-rulings presented to the Society, and made by Mr. H. J. Grayson, of Melbourne; these were mounted in realgar, a medium possessing a refractive index of 2·5, which caused the lines to stand out with great distinctness. Two were micrometers and two were test plates. The micrometer rulings had been critically measured, and were found to be accurately and evenly spaced; and the test plates were beautifully ruled. There was also a specimen of ruling suitable for a diffraction grating. Mr. Grayson had likewise sent a number of slides of test diatoms mounted in realgar, and some mounted in styrax, for comparison. The slides showed no signs of crystallisation; they had stood the heat and rough handling in the post from Melbourne, and the great heat of the past summer; and Mr. Grayson said that, from the method adopted by him, there was no fear of crystallisation taking place.—A paper by Mr. J. Newton Coombe, "The Reproduction of Diatoms," was read by the Secretary, and was illustrated by a series of lantern slides. Mr. Bennett said the paper appeared to throw a new light on the various modes of reproduction, and seemed to point to the removal of the diatoms from the Protophyta to a position among the Conjugatae.—Part iii. of Mr. Millett's "Report on the recent Foraminifera of the Malay Archipelago" was taken as read.

Manchester.

Literary and Philosophical Society, October 18.—J. Cosmo Melvill, President, in the chair.—Mr. J. J. Ashworth exhibited a plant and cobs (both ripened and immature) of Indian corn (*Zea maïs*) grown at Wilmslow, Cheshire. Mr. Charles Bailey made some observations on the exhibits, remarking especially on the inflorescence and fructification of the plant, and on its geographical distribution.—The President communicated a paper by Mr. Peter Cameron, entitled "Hymenoptera Orientalia, or contributions to a knowledge of the Hymenoptera of the Oriental zoological region," Part viii. The author described a large number of new genera and species of hymenopterous insects from the Khasia Hills in the Eastern Himalayas, a district which has not hitherto been worked for its Hymenoptera. The specimens were collected by the natives, some of whom make excellent collectors, but who mostly confine their attention to large or medium-sized species. That the species inhabiting this region must number many thousands, is evident from the fact that in the comparatively small district of Sikkim there are found about 600 species of butterflies and (probably) thousands of moths.

Edinburgh.

Mathematical Society, November 11.—Mr. J. B. Clark, President, in the chair.—Mr. George Duthie communicated a paper on "Systems of circles analogous to Tucker's circles," by Mr. J. A. Third, and Mr. W. L. Thomson read a paper on the "Geometrical theory of the hyperbolic functions."—On the motion of Prof. G. A. Gibson, a committee was appointed to consider the treatment of proportion in elementary mathematics.—The following were elected office-bearers for the current session:—President: Dr. Alex. Morgan. Vice-President: Mr. R. F. Muirhead. Hon. Secretary: Mr. J. W. Butters. Hon. Treasurer: Mr. F. Spence. Editors: Mr. John Dougall, Mr. Charles Tweedie, Dr. C. G. Knott. Committee: Messrs. J. D. H. Dickson, Geo. Duthie, and A. Lindsay.

Paris.

Academy of Sciences, November 14.—M. Wolf in the chair.—Observations of the meteor swarm, by M. Loewy. Owing to the unfavourable weather, on the nights of November 10 and 11 only two meteors belonging to the group of Leonids were observed.—Observations on the sun, made at the Observatory of Lyons with the Brunner equatorial during the second quarter of 1898, by M. J. Guillaume. The results are given in three tables, showing mean area of spots, and their distribution in latitude and longitude respectively.—On the development of uniform functions in Taylor's series, by M. Émile Borel.—On an indeterminate equation, by M. Carl Störmer.—On the production of crystallised tungsten by electrolysis, by M. L. A. Hallopeau. The electrolysis of lithium paratungstate gives metallic tungsten in a well crystallised state. The corresponding sodium and potassium salts yield only tungsto-tungstates on similar treatment.—Volumetric estimation of boric acid, by M. Copaux. The method used is developed from those proposed by Gasselin, R. Thomson, and Barthe, the titration being carried out in presence of alcohol and glycerol, helianthin and phenolphthaleïn being used as indicators. The analyses of borax and ethyl borate quoted are very satisfactory.—New halogen derivatives of guiacol and veratrol, by M. H. Cousin. Trichloro-guiacol, dibromoguiacol, tetrabromoguiacol, trichloroveratrol and tribromoveratrol have been prepared and described.—On a new sugar accompanying sorbite, by MM. Camille Vincent and J. Meunier. When sorbite is crystallised from aqueous solutions, the new sugar remains in the mother liquors. These are then fermented by the sorbose bacterium, which oxidises the residual sorbite, and the sugar is then extracted from the syrup by benzaldehyde in presence of sulphuric acid. The sugar obtained from this is an octite, $C_8H_{18}O_8$, and has not been crystallised. A comparison of its properties with those of sorbite shows that the substances are quite distinct.—Derivatives of natural methylheptenone, by M. Georges Leser. The reaction between sodium, acetic ether, and natural methylheptenone has been studied, and a condensation product $C_{16}H_{26}O$ isolated and analysed.—Volumetric analysis of acetaldehyde, by M. X. Rocques. The results obtained by the method previously given by the author have since been found to vary with the temperature. To obtain exact results it is necessary to carry out the reaction in closed vessels at 50° C.—Estimation of diabetic sugars by the polarimeter, by the reduction coefficient, and by fermentation, by M. Frederic Landolph. The author distinguishes three classes of diabetic sugars, which are clearly indicated by the relations existing between the amount of Fehling's solution reduced, the rotatory power, and the amount of carbon dioxide produced on fermentation.—Some general preliminary conclusions on humic coals, by M. C. Eg. Bertrand.—On the mode of formation of indigo in the methods of commercial extraction, by M. L. Bréaudat. The suggestion that micro-organisms play a part in the indigo fermentation, would appear to have no foundation. The plant especially studied, *Isatis alpina*, contains a hydrolysing diastase and an oxydase. In presence of water, the former splits up indican into indigo-white and indiglucin, and the latter oxidises the indigo-white in presence of an alkali to indigo.—On the absorption of the halogen salts of potassium by plants, by M. E. Demoussy. Plants growing in solutions containing potassium chloride, at first rapidly absorb the salt, but this absorption slows down and finally ceases. Sodium bromide is also absorbed, but not the iodide.—Researches on lesions of the nervous centres produced by experimental hyperthermy, by M. G. Marinesco.—On early lesions of the nervous centres in hydrophobia, by M. V. Babes. Hydrophobia produces cellular and vascular lesions of the grey matter, which can be made out one or two days before the appearance of the first rabic symptoms.—Observations on the general course of histogenesis and organogenesis, by M. J. Kunstler.—On burrowing in the Homaridae and Thalassinidae, by M. Georges Bohn.—On the development of some species of *Trochus*, by M. A. Robert.—Absorption of carbohydrates by roots, by M. Jules Laurent. A maize plant will grow and gain weight in an atmosphere free from carbon dioxide, if supplied with glucose. Sunlight, however, is necessary for this assimilation.—On the

vertebrate layer of the asphalte mines of Pyrimont (Savoy), by M. Ch. Depéret.—On the green ray, by M. L. Libert. Notice of the appearance of this phenomena at Sainte-Adresse.

NEW SOUTH WALES.

Linnean Society, September 28.—Prof. J. T. Wilson, President, in the chair.—On the mountain ash of Southern New South Wales, by Henry Deane and J. H. Maiden.—On two new species of *Eucalyptus* from New South Wales, by R. T. Baker. Two well-defined species, remarkable for the chemical constituents of their oils, belonging to the group Renantherae, and known vernacularly as "Silver Top Stringybark" and "Messmate" respectively, are recorded in this paper. For the first of the two the name *E. laevopinea* is suggested because the oil obtained from the leaves consists largely of pinene which is *laevo-rotatory*, and the name *E. dextropinea* is proposed for the second species owing to the oil consisting largely of pinene, which in this case is *dextro-rotatory*. In both the specific rotation is greater than in the well-known pinenes obtained from the Coniferae, although chemically identical.—A description of certain objects of unknown significance, formerly used by some New South Wales tribes, by Walter R. Harper.—Mr. W. W. Froggatt exhibited a twig from a fruit-tree obtained near Sydney, which had 150 eggs of an undetermined grasshopper attached to it in a double row; also a number of the newly-hatched young insects. These were of interest because of their remarkable resemblance to a common ant (*Iridomyrmex purpureus*, Sm.), which is plentiful in the orchards and bush about Sydney, hunting over the trees for food. It seems probable that this may be a case of protective mimicry, the grasshoppers perhaps being protected against the attacks of insectivorous birds, and the ants also deceived.—Mr. J. Mitchell, of Newcastle, forwarded a brief note announcing his discovery of the print of an insect's wing in the shale overlying the Yard Seam of coal at the base of Flagstaff Hill, Newcastle. There was, he believed, no previous record of the presence of insect remains in rocks of the Permo-Carboniferous Age in New South Wales. He hoped to be able to exhibit the specimen at a future meeting.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 24.

ROYAL SOCIETY, at 4.30—Preliminary Note on the Spectrum of the Corona: Sir J Norman Lockyer, K.C.B., F.R S—On the Condensation Nuclei produced in Gases by the Action of Röntgen Rays, Uranian Rays. Ultra-Violet Light, and other Agents: C. T. R. Wilson.—The Origin of the Gases evolved on Heating Mineral Substances, Meteorites, &c.: Dr, M. W. Travers.—Memoir on the Theory of the Partitions of Numbers: Part 2: Major MacMahon, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Rotatory Converters: Prof. S. P. Thompson, F.R.S.

FRIDAY, NOVEMBER 25.

PHYSICAL SOCIETY, at 5.—On the Properties of Liquid Mixtures: R. A. Lehfeldt.—On certain Diffraction Fringes as applied to Micrometric Observations: L. N. G. Filon.

MONDAY, NOVEMBER 28.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—A Year on Christmas Island: Chas. W. Andrews.

IMPERIAL INSTITUTE, at 8.30.—Gold-Mining in Victoria: Ernest Lidgey.

SOCIETY OF ARTS, at 8.—Acetylene: Prof. Vivian B. Lewes.

INSTITUTE OF ACTUARIES, at 5.30.—Inaugural Address by the President, H. W. Manly.

TUESDAY, NOVEMBER 29.

ZOOLOGICAL SOCIETY, at 8.30.—Further Notes on the Amazonian Lepidosiren: Dr. E. A. Goeldi.—On the Anatomy of Adult and Foetal Specimens of *Pedetes caffer* as compared with that of the *Dipodidae*: F. G. Parsons.—On a New Species of Spiders from Trinidad, West Indies: F. O. Pickard-Cambridge.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Effect of Subsidence due to Coal-Workings upon Bridges and other Structures Stanley Robert Kay.

WEDNESDAY, NOVEMBER 30.

SOCIETY OF ARTS, at 8.—Photographic Developers and Development; C. H. Bothamley, F R.S.

THURSDAY, DECEMBER 1.

LINNEAN SOCIETY, at 8.—On the Biology of *Agaricus velutipes*, Curt.: R H. Biffen.—On the Gastric Glands of the Marsupialia: Jas. Johnstone.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—The Oxidation of Polyhydric Alcohols in presence of Iron: H. J. H. Fenton and H. Jackson.

FRIDAY, DECEMBER 2.

GEOLOGISTS' ASSOCIATION, at 8.—Contributions to the Geology of the Thame Valley: A. M. Davies.

INSTITUTION OF CIVIL ENGINEERS, at 8—The Sunlight Gold-bearing Reef, Lydenberg, Transvaal: Charles Benjamin Saner.

QUEKETT MICROSCOPICAL CLUB, at 8.

BOOKS, PAMPHLET, SERIALS, &c., RECEIVED.

BOOKS.—Deutscher Botaniker-Kalendar für 1899 (Berlin, Borntraeger).—Symbolae Antillanae seu Fundamenta Florae Indiae Occidentalis: editit I. Urban, Vol. 1, Fasc. i. (Berlin, Borntraeger).—Society for the Promotion of Engineering Education: Proceedings of the Fifth Annual Meeting (Lancaster, Pa.).—Transactions of the American Pediatric Society, Ninth Session (New York).—Psychologische Untersuchungen über das Lesen: B. Erdmann and R Dodge (Halle, Niemeyer).—Animals of To-day, their Life Conversation: C. J. Cornish (Seeley).—Colour in Nature: Dr. M. I. Newbigin (Murray)—Among the Celestials: Captain F. Younghusband (Murray).—The Five Windows of the Soul: E. H. Aitken (Murray).—Australian Legendary Tales: collected by K. L. Parker (Nutt).—More Australian Legendary Tales: collected by K. L. Parker (Nutt).—From Sphinx to Oracle: A S. White (Hurst).—Essai d'une Philosophie Nouvelle: L. Ribert (Paris, Alcan).—Pflanzen-Geographie auf Physiologischer Grundlage: Prof. A. F W. Schimper (Jena, Fischer).—Quick and Easy Methods of Calculating: R. G Blaine (Span)—The Story of Geographical Discovery: J. Jacobs (Newnes).—Text-book of Algebra: Drs. Fisher and Schwatt, Part 1 (Philadelphia, Fisher).—Monographieen Afrikanischer Pflanzen Familien und Gattungen: i. A. Engler; ii. E. Gilg (Leipzig, Engelmann).

PAMPHLET.—Experiments on the Pressures and Explosive Efficiency of Mixtures of Acetylene and Air (Leeds, Jowett).

SERIALS.—Atlantic Monthly, November (Gay).—Proceedings of the Royal Society of Victoria, Vol. xi. Part 1 (Melbourne).—Proceedings of the Indiana Academy of Science, 1897 (Indianapolis).—Journal of the Franklin Institute, November (Philadelphia).

Public School Protractor Scale (Macmillan).

THE SHIVERING EARTH.

Seismology. By John Milne, F.R.S., F.G.S. Pp. xvi + 320. (London: Kegan Paul, Trench, Trübner, and Co., Ltd.)

PROFESSOR MILNE spent more than twenty years in Japan. When he went there he was experienced as a miner and geologist; and had spent years in Newfoundland, Iceland, Arabia, Siberia and Mongolia as an explorer. He was Professor of mining and geology, and later, of seismology, but for twenty-three years he seems to have devoted himself to the one subject, seismology. The *Transactions* of the Seismological Society of Japan are mainly of his writing. He has published books and numerous papers in England. Through his influence the Japanese Government has established many seismological observatories. He seems to have made a thorough trial of hundreds of seismometers. He enlisted the observational services of many of the foreigners living in Japan. As Secretary of the British Association Committee he has written numerous valuable reports. He has induced all the engineers and architects in Japan to build in accordance with the conclusions drawn by him from his observations. During the last two years he has been the means of establishing twenty-three seismological stations over the world, and he considers it his duty to keep in communication with them all.

In all these years he seems to have missed no chance of supplementing his own mathematical and scientific knowledge by that of anybody whom he could induce to study his subject. He has a pleasant style, and knows from experience as a popular lecturer exactly how his subject may be made interesting to the general reader, and the result is a very readable book which probably contains all that is worth knowing on this subject at the present period of its development. Twenty such volumes might have been written if the author had cared to touch on all the crude speculation of quasi-scientific workers which has from time to time been published.

The earth, about whose interior we know as much as Carlyle's ephemera knew about the lunar theory, is intensely hot under enormous pressure at all depths below a few miles. As the inside cools it contracts, and the crust must also get smaller, and so we have all sorts of crumpling and buckling actions going on slowly always; gradual changes of slope which show themselves mainly by changes of sea level. A small vertical fall or rise in water level may accompany enormously great changes in land area. A lift of all the Tertiary mountainous districts to an average height of 4000 feet would seem to have required only a vertical fall of the water level of twenty-six feet, although the actual breadth of land exposed at coasts may possibly have been very great; and by the possible repeated exposure and submergence of great areas of sedimentary beds, accompanying the probable discontinuous rise of the mountains. Prof. Milne throws an unexpected light on the well-known fact that the great mountain-forming epochs in geological history, epochs of great brady-seismical and volcanic activity, have a close chronological identity with the periods of coal formation. That there has been crumpling in the past is evident enough; but it is interesting to note how we are getting evidence that it is still going on; that the surface of the earth almost everywhere is changing in slope, and falling and rising. Not only have we tilting due to mere change of atmospheric pressure; to rain being better retained by some kinds of crops than others; to the attraction of the moon; to the melting of polar ice; to the erosion of land by sea and river; and the more or less continuous slipping of soil on steep slopes, but to a far more important extent locally, by the deposition of sediment at the mouths of rivers. Every now and again the bending crust undergoes fracture, especially at the bases of monoclines. Some kinds of rock keep fracturing continually; others yield without fracture for long times, and when they fracture they do it with violence; faults are suddenly formed, possibly at great depths, and the motion, the sudden shiver or vibration is transmitted to every part of the earth. If the fault occurs near the surface of the earth, other evidence of it appears than the temporary passage of an imperceptible or terrifying shiver; in minor dislocations, horizontal displacement and sometimes actual contraction. Thus in Japan in the Neo valley in 1891 some plots of ground were diminished 30 per cent. in breadth; river beds were permanently narrowed; forests slipped down from mountain sides to block up valleys and form great lakes; the whole land on one side of the valley lowered in level, and a boundary ridge of high mountains with it. Any one who looks at maps of the world published by the Electric Cable Companies will notice how, along the west side of South America, and at many places elsewhere, a cable is not brought along the coast directly from one place to another; for safety it goes out to sea a great distance. If we did not have actual evidence of it, we could not believe in the numerous sudden large changes of sea bottom which occur, fracturing submarine cables. Except in Japan no people are so enthusiastic in the establishment of Prof. Milne's observatories as those interested in such cables. In 1888 the simultaneous fractures of three submarine cables between Australia and Java by an earthquake caused Australia to mobilise its naval and military forces; and on several occasions Prof. Milne has been able to answer questions of the Colonial Government as to the cause of fracture of cables.

The earthquake or shiver is transmitted to all parts of the earth. The student of acoustics may imagine how the complicated system of vibration gets reflected and refracted and changed in character as it travels, and how different the complete record must be at a place near to the primary disturbance from what it is six thousand miles away, and how anywhere it depends on the local character of the ground. And yet, in spite of this complication, there are interesting general rules which have been derived by the author from observation. A disturbance which has travelled 6000 miles, is recorded by preliminary simple tremors which may have periods of 5 to 12 seconds, the more decided movements having periods of from 20 to 40 seconds. At places nearer, the motion is more complicated; the preliminary tremors have periods of from ·04 to ·2 sec.; the decided movements, say with ranges of motion 10 to 20 mm., have

periods of 2 to $2\frac{1}{2}$ sec.; movements of 1 to 1·5 mm. range, which constitute the greater part of many records, have periods of about 1 sec. The record ends in simple vibrations of periods 1·5 to 4 seconds, like waves of the ocean after a storm.

It is to be presumed that magnetic and other messages are constantly passing to us through the earth, which, if we could only read them—if we knew anything about the cause of terrestrial magnetism, for example—would tell us something about the inside of our habitation. Earth shivers which have travelled from Japan to England seem to be the only messages coming to us through the earth's body which we are able to understand, and which can give us at present any knowledge of what that body is like.

Vibrations from gunpowder explosions in the earth are found to travel faster if the explosions are more violent. Mallet's experiments gave velocities of from 250 to 500 metres per sec. The velocities deduced from the Hell-Gate explosion vary from 1300 metres per second to 6200. More sensitive apparatus records higher velocities, because it has been acted upon by the smaller tremors, and these travel faster than others. Prof. Milne gives a list of earthquake speeds actually observed.

Counting time from the first record anywhere and distance from the place of this first record, measuring either by an arc on the earth's surface, or by a chord, we may look upon the following speeds as not unusual.

Distance from origin.		Apparent velocity in kiloms. per sec.	
In degrees.	In kiloms.	Along arc.	Along chord.
20	2,200	2 to 3	2 to 3
50	5,500	5	5
80	8,800	8	7·5
100	11,100	10	8·8
120	13,200	12 ?	10 ?
160	17,700	16 ?	10·5 ?

The more decided state of motion which arrives with more or less of definiteness of transition after the tremors, travels at a much slower rate (1 to $3\frac{1}{2}$ kiloms. per sec.), and hence the time of duration of the preliminary tremors tells us the distance to the origin. Hence when a seismograph record is made in the Isle of Wight, the distance through which the motion has travelled may generally be estimated with some accuracy, and hence also the violence of the initial disturbance may be guessed at.

It seems to be out of the question that the preliminary tremors have travelled on the earth's surface either as Lord Rayleigh's surface waves or as distortional waves or condensational waves. We can only understand their propagation if we imagine the stuff in the earth at great depths as having cubic elasticity very much greater than that of the best steel, but it is not so easy to understand how such enormous elasticity can be possessed by it. Those students of nature who assume that the behaviour of rock on the earth's surface enables them to speak with easy certainty as to the behaviour of rock at enormous pressure and temperature, must surely find some difficulty in understanding the above observations, just as there are celestial phenomena which must surely disturb the equanimity of the unimaginative persons who apply their farthing rush-light laboratory experience without modification or reserve to all the phenomena of the universe.

The author describes the instruments used now to note or accurately record or measure the motion of the ground or of any point in a structure when an earthquake or shiver passes. The invention of a good instrument for each kind of motion has exhausted much mathematical and inventive genius. It will be found that Prof. Milne is wonderfully fair to other inventors. There seems still to be some doubt as to how much of the motion recorded as horizontal motion of the ground is perhaps something different, an effect of tilting of the instrument. The study of the whole subject has undoubtedly added to our knowledge of vibration phenomena, and I should think that this book will be found of great value by young engineers in charge of electric light stations, where the most important problem of the present time is how to protect citizens from the annoying vibration of reciprocating steam engines. At some future period it may enter the minds of manufacturers of engines that the lineal descendant of Newcomen's slow reciprocating pumping engine is not perhaps the best kind of quick speed motor to use in a thickly inhabited district, and that although passengers by steamer must put up with such a nuisance because there is no forbidding law, the manufacturers of electric energy may easily be compelled to reform their methods of working. The study of all such vibration can be carried on only by the use of instruments such as Prof. Milne describes They have already given useful information in showing how wasteful of coal a badly balanced locomotive may be; in picking out badly constructed parts of the permanent way in railways, in detecting loose parts in bridge construction, and, more important than any of these, they are now giving us information as to the dangerous vibrations of some bridges when trains pass over.

One important result that seems to be gradually establishing itself in the minds of observers is that the number of shakes s per day (vigorous enough for record on a particular kind of instrument) at any place at the time t days after a large earthquake, and at the distance n miles from the epicentre, is a not very complex sort of function of n and t. From the numbers given by Prof. Milne, I venture to say that the law for the after-shocks of the 1891 earthquake is something like

$$s = 117 \div \left(e^{t/31 + n/27} \right),$$

an expression that is worth some study as representing fairly well the result of observation. An enormous amount of labour has been given to the search for a periodicity in earthquakes. It does seem that seismic and barometric maxima coincide, and possibly because of this, or because of snow accumulation, there is greater seismic activity in winter than in summer, although more destructive earthquakes seem to occur in summer. The much looked for dependence of seismic activity on the moon's position is not yet established so well as the

annual and semi-annual periodicities; nor has an effect of the ocean tides yet shown itself. It does not seem to be established that there is any connection between earthquakes and electric or magnetic or auroral phenomena. Slow changes of slope of the earth's surface at any place are continually going on; these are more pronounced in the direction of the dip of certain strata. Those that are mostly of importance in astronomical observatories are due to differences in soils and crops in retaining power for moisture; and Prof. Milne seems to have made a careful study of soils, not merely in regard to their absorption and retention of moisture from the air, but also in regard to their condensation of vapour coming up from beneath, and the results of his observations and experiments seem as if they might be of value to agriculturists.

The author dwells at some length upon curious earth pulsations and earth tremors which seem to be unconnected with earthquakes. They occur everywhere, and their study ought to be of importance to all who have an interest in astronomical or magnetic observatories or in exact measurement of any kind; for example, in careful weighing.

Earth *pulsations* have periodic times of two to three minutes, or even ten or more minutes, beginning and ending for no known reason, lasting for one to three hours. Are they connected with the curious sea-swells of the Pacific which recur annually at very high tide and last for twenty-four hours? Then there are the curious earth *tremors*, not to be confounded with the effects of traffic on roads—they are storms lasting eight to twelve hours, sometimes two to three days, never less than three hours.

No doubt in some cases mere air currents inside the covers of the instruments produce some of the effects observed, but in most cases they are real earth tremors, due possibly to expansions and contractions of the soil by heat and other causes, but this will not explain everything; nor will meteorological changes; nor will winds acting upon the ground in the neighbourhood. The level and slope of ground change perpetually, and the changes seem never to be quite continuous. Prof. Milne cites many observations which show the great importance of the study of these earth tremors in connection with changes of barometric pressure and the escape of fire-damp in mines.

I know that what I have here jotted down after reading this most interesting and valuable scientific work will give only a very poor idea of its contents, and the author will consider that his views are described very crudely. But what can be done in a short notice of such a book? Every sentence in the book contains the result of much thought and observation, and yet it is a book which is just as easy to read as the report of a popular lecture. One has also the feeling that the writer is appealing for sympathy and co-operation of all kinds, without which his great work in the establishment of observatories cannot go on; it is the kind of appeal that one reads between the lines of a traveller's book sometimes, an appeal that the author does not know that he is making. It certainly adds to the interest of an already interesting subject.

JOHN PERRY.

COFFEE AND INDIA-RUBBER IN MEXICO.

Coffee and India-rubber Culture in Mexico. Preceded by Geographical and Statistical Notes on Mexico. By Matias Romero. Pp. xxvi + 417. (New York and London: G. P. Putnam's Sons, The Knickerbocker Press, 1898.)

AT a time when both the products mentioned at the head of the title-page of this book are attracting a great amount of attention as important cultural industries suitable for many of the British Colonies, as well as for other parts of the world, and when india-rubber or caoutchouc especially continues to increase in value and demand, anything bearing on the cultivation of these plants is sure to be eagerly sought after.

It would almost seem that in selecting the title for his book Mr. Romero had in view the probability of catching readers by reversing the order of its correct title, which should more properly stand as "Geographical and Statistical Notes on Mexico: followed by Chapters on Coffee and India-rubber Culture," for in a volume of 417 pages it is not till we arrive at p. 281 that the consideration of the cultivation of coffee is commenced, and it is finished at p. 359. Again, with india-rubber this subject is disposed of in the thirty-three concluding pages of the book. The statistical portion of the book, therefore, occupies its greatest bulk, and is placed first in order. Besides which Mr. Romero candidly says in his introduction that the papers on coffee and rubber were written about a quarter of a century ago, and simply appear now as a translation without any attempt at bringing them up to date; while the geographical and statistical notes were only just published when the introduction was written in January last.

It may be of some interest, as showing how the book has been put together, to quote a few paragraphs from the author's introduction. At p. v. he says, speaking of the article on coffee:

"I published in Mexico three editions of my manual, correcting and adding to each new one, the last one being published in July 1874. There was at the time no interest in coffee culture, and very little attention was therefore paid to my manual. By the advice of a friend, I placed in a book-store about fifty copies on sale, and four or six years later only two or three had been sold."

Again, on p. vi. Mr. Romero gives his reasons for not bringing his matter up to modern times as follows:

"I am very sorry that my present engagements have prevented me from revising this paper up to date; that is, changing such views expressed in the same as my experience has taught me not to be entirely correct, at least, in so far as other regions outside of the southern coast of Chiapas are concerned, as that would require more time than I can afford; and, in my inability to do that work, I prefer to use the paper I wrote long ago exactly in the shape in which it then came out. Since that time all circumstances and conditions of coffee raising have materially changed."

In the introduction to the paper on rubber culture Mr. Romero puts forward the same reasons for not revising his paper, which he says:

"I publish now exactly as it came out over a quarter of a century ago."

Under such circumstances nothing can be said by way of criticism, except to remark that if all Mr. Romero's matter is of the same quality as his description of rubber-yielding trees on p. 378, the book stands in much need of careful revision. J. R. J.

OUR BOOK SHELF.

Practical Mechanics: an Elementary Manual for the Use of Students in Science and Technical Schools and Classes. By Sidney H. Wells, Wh.Sc., A.M.Inst.C.E. Pp. xii + 220. (London: Methuen and Co., 1898.)

THIS book is really a handbook for students who make those quantitative experiments in a mechanical laboratory which are now part of the Applied Mechanics Course of the Science and Art Department. The laboratory system of teaching this subject has passed through all its trials, and has taken its rightful place, not merely in evening science schools, but in the engineering classes of the most pretentious technical institutions in every part of the world. It seems to us that this little book will prove to be a useful guide to teachers. A good teacher will arrange his own methods; he will probably design much of his own apparatus, and he will write out with his own hands the instructions to students using the apparatus, giving up this most important part of his work to no lieutenant, however clever and ingenious. He will, in fact, arrange his apparatus to suit his students and the character of the rest of his teaching. Even he, however, must welcome a description of the apparatus and its uses which have suggested themselves to such an experienced teacher as Mr. Wells.

We have one objection to this book, and it is serious. The apparatus illustrates static laws of force, and force is recognised as a space rate of the doing of work: but we find nowhere any attempt to give to students the fundamental notion of mechanics, that force is a time rate of change of momentum. To supplement what Mr. Wells has given, twenty pieces of well-known apparatus might easily be mentioned which require no special design to fit themselves to quantitative laboratory work, and without a description of such apparatus it seems to us that this book is very incomplete. J. P.

Skiagraphic Atlas: showing the Development of the Bones of the Wrist and Hand. For the use of students and others. By John Poland, F.R.C.S. Pp. 40 and Plates. (London: Smith, Elder, and Co., 1898.)

THIS handy volume is a reprint of a portion of a larger work by its author ("A Practical Treatise on Traumatic Separation of the Epiphyses." London: Smith, Elder, and Co., 1898) which deals with the skiagraphy of the wrist and hand, as revealing *in situ* the stages in ossification of their supporting skeleton. There are nineteen skiagraphs in all, which represent successive phases in the process named at periods between and including the first and seventeenth years, and as a frontispiece there is added a woodcut delineating the isolated hand skeleton at fifteen and a half years, with each bone fully named for comparison with the body of the work. The skiagraphs, with the exception of that of the hand of the author's son, taken by Mr. Swinton, are the work of Mr. C. Webster, and all are excellent and among the best we have seen. A short introductory account is given of the anatomy and growth periods of the several bony centres, with accurate measurements where necessary; and each illustration is accompanied by a brief statement of its salient features. Since, concerning these, some of the author's observations are at variance with what is customarily taught, his book cannot fail to be a useful work of reference both to the anthropotomist and surgical anatomist. The author remarks in his preface that he hopes "in the near future all the bones of the body may be thus portrayed"; and if he should be as successful with the pelvis as he has been with the hand, we would earnestly recommend him and his publishers to lose no opportunity of making the work known to the general public, and of thus forcing home facts which may perchance be brought to bear upon the too prevalent tendency towards premature cycling by young children, which, if not checked by some such salutary means, would seem likely to threaten the rising generation with disaster.

A Manual of Bacteriology, Clinical and Applied. By Richard T. Hewlett, M.D., M.R.C.P., D.P.H., &c., Assistant in the Bacteriological Department, British Institute of Preventive Medicine. Pp. viii + 439. (London: J. and A. Churchill, 1898.)

THIS book should take a very creditable place amongst the smaller manuals of bacteriology which have appeared in recent years. The author has had considerable acquaintance both with the practice and the teaching of his subject, and he has formed just conclusions as to what he should include in his book, and what he should omit. He has included those methods and facts which it is essential for the student to know, with a sufficient amount of the abstract science to enable him to grasp methods and facts intelligently: he has omitted a great mass of scientific detail with which it is needless to burden the student at the outset. The book is thus of moderate compass; it is eminently practical, and its aims are directed to clinical medicine and hygiene in particular. The usual introductory chapters are short, but explicit and accurate. Perhaps the chemistry of bacteria and their products might have been accorded more space, in view of its increasing importance; but the subject of nitrification is well and clearly treated. Methods of cultivation and staining are so plainly put, that the volume becomes a sufficient handbook for laboratory work. The structure and mode of use of oil-immersion lenses is very properly described and illustrated by diagrams. A short chapter on immunity and antitoxins puts this difficult subject as lucidly before the student as the present state of knowledge permits. The principal pathogenic organisms are then described in detail in some 150 pages. The facts are well put, and appear up to date, though the order in which the different bacteria are dealt with is somewhat erratic. Thus *Bacillus aerogenes capsulatus* appears amongst pyogenic and septic organisms; while *B. oedematis maligni*, its close ally, appears nine chapters further on amongst the anaërobes. The enormous importance of streptococci in clinical medicine should, we think, have led to something more than their summary treatment in about four pages. The writer discusses the question of the "pseudo-diphtheria" bacillus at some length, and evidently inclines to the view that it may be only a modified diphtheria bacillus. Under the head of scarlet fever the views of the veterinary profession as to the nature of the so-called "Hendon disease" are adopted in preference to those of the Local Government Board experts, and this without any adequate discussion of the facts: it would have been wiser, in a book of this sort, to omit the question altogether. In the concluding chapters Dr. Hewlett gives a short account of the bacteriology of water, air, and soil, and also of sewage, milk, &c., with a description of the chief methods employed. Antiseptics and disinfectants form the subject of another chapter, and the volume concludes with an account of antitoxins, vaccines, and other bacterial remedies. The illustrations are mostly reproductions of microphotographs, and are fairly good, though not unduly numerous. The book appears to us, on the whole, to be one of the best of the smaller manuals on bacteriology with which we are acquainted, and may be taken by the student as a trustworthy guide for laboratory work.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Asymmetry and Vitalism.

THAT portion of Prof. Karl Pearson's letter in NATURE of Nov. 10 which deals with chemical problems is largely based on misconceptions of the meaning of terms used by chemists. Thus, after quoting a statement of mine regarding optically active compounds, he says: "An optically active compound means merely a preponderance of one kind of enantiomorph." That is precisely what it does *not* mean; that would be an optically active *mixture*. No chemist ever uses the word "compound" when he means "mixture"; I meant one kind of enantiomorph and one only. Moreover, I explained this point in detail in my first reply. Prof. Percy Frankland, as a chemist, has of course found no difficulty in following my meaning; he says that the question which I raised was: "the possibility of producing, without the interference of a living agency, an optically active substance *unaccompanied by its enantiomorph*." A great part of Prof. Pearson's letter is therefore devoted to combating an opinion which I never expressed, and I am consequently relieved from the necessity of further discussing this part, or of calling attention to similar misconceptions which it contains. One point, however, I must notice. Prof. Pearson complains that I have supposed that he meant "twenty" molecules and no more, when in reality he referred to twenty tosses of a coin; and he adds that he was willing to assume the formation of a million molecules. I was led to take his words in the former sense by my impression—as it now appears, a mistaken impression—that he really understood that I was arguing about *single* asymmetric compounds; and I imagined that he purposely assumed the formation of only a small number of molecules in order that they might conceivably be all of one kind of asymmetry.

The part of the letter which I wish especially to consider is that in which Prof. Pearson suggests a hypothetical symmetric mechanism by which he believes a separation of enantiomorphs might be effected. This suggestion, if valid, strikes at the root of a generally accepted principle of molecular asymmetry. I can sincerely say that it is with the utmost diffidence that I venture to call in question any result that Prof. Pearson has arrived at by a mathematical process. But in the present case, I have tried in vain to follow his reasoning; whilst, if I work out the problem in my own way, I arrive at a conclusion exactly the opposite of his. I have no choice, therefore, but to state my results, and to ask Prof. Pearson to correct me if I am wrong.

The tetrahedral representation of two enantiomorphous molecules, each containing a single asymmetric carbon atom, is given in my address (NATURE, vol. lviii. p. 455). The tetrahedra (Figs. 1 and 2) are assumed to be irregular; the four different atoms or groups are situated at different distances from the central carbon atom to which they are attached; the two tetrahedra are enantiomorphous. It must be carefully borne in mind that in these two structures *all corresponding molecular dimensions are identical*; the two structures differ only in their opposite asymmetry.

Prof. Pearson imagines a thin cylindrical sheet of optically inactive mixture to be whirled round the axis of the sheet; and he argues that owing to the position of the centroid in these enantiomorphous tetrahedra, the one kind might be in *stable* equilibrium when, say, their X′ angle sets inwards, and the other, when this sets outwards; "or at least some similar like difference of positions will differentiate like from unlike enantiomorphs." Then, on allowing a strip of the cylindrical surface placed horizontally to fall through a viscous fluid, the difference of resistance caused by this difference of position may effect a separation of the two kinds.

As I have said, I am unable to follow this reasoning. I should discuss the problem as follows:

Let H, X′, Y′, Z′ (Figs. 1 and 2, *loc. cit.*) represent the four different atoms or groups attached to the central carbon atom; and, as regards their masses, let $H < X'$, $X' < Y'$, and $Y' < Z'$.

Then, supposing a thin cylindrical sheet of substance consisting of equal numbers of the two enantiomorphous tetrahedral forms to be whirled about its axis, each tetrahedron, whether right-handed or left-handed, will be in stable equilibrium when the distances of the foregoing groups from the axis of rotation of the sheet are in the order H, X′, Y′, Z′. Therefore the edge Y′ Z′ of either tetrahedron will be nearer to the outer surface of the sheet than the edge H X′; and each of these edges will be inclined towards this outer surface so that the ends Z′ and X′, of these edges, are respectively nearer to it than the ends Y′ and H; and the inclination of corresponding edges will be the same in both tetrahedra. A line joining the centroid of the face H X′ Y′ with Z′, and produced through Z′ to meet the outer surface of the sheet, will form the same angle with this surface, whether the tetrahedron be right-handed or left-handed. Right-handed and left-handed molecules will therefore be affected in exactly the same manner when a strip of the cylindrical surface is placed horizontally and allowed to fall through a viscous fluid; and no separation of the two kinds will occur. The "difference of positions" which Prof. Pearson demands, does not extend beyond the fact that a continuous curve passing towards the surface of the sheet through the groups H, X′, Y′, Z′ in succession, will in the one set of tetrahedra describe a right-handed, in the other a left-handed helix.

I am unable to arrive at any other conclusion than the foregoing.

Prof. Percy Frankland's suggestion of a mechanism by which, starting with a single asymmetric molecule, an optically active compound might be produced unaccompanied by its enantiomorph, practically coincides with that published a little later by Mr. Strong. Such an action is, as I admitted in noticing Mr. Strong's communication, certainly conceivable, although, as an actual process occurring under chance conditions, it is exceedingly improbable. I regret that I overlooked the possibility of such an action.

Prof. Frankland's other suggestion is that, prior to the existence of life on the earth, "the asymmetry of solar radiation may originally have determined the exclusive synthesis of one enantiomorph." I had already considered this possibility. It seems to me that the earth's rotation, to which this asymmetry of solar radiation is due, is so slow as compared with the atomic and molecular motions involved in the production of chemical compounds, that it is difficult to understand how it could perceptibly impress its asymmetry on chemical action.

Although, in view of the arguments adduced by Prof. Percy Frankland and Mr. Strong, I no longer venture to speak of the *inconceivability* of any mechanical explanation of the production of *single optically active compounds asymmetric always in the same sense*, I am as convinced as ever of the *enormous improbability* of any such production under chance conditions. The processes suggested by Prof. Frankland and Mr. Strong are purely hypothetical and are likely to remain so.

The University, Aberdeen, November 17. F. R. JAPP.

Early History of the Great Red Spot on Jupiter.

HAVING collected a number of observations and drawings of objects bearing a suggestive resemblance to this feature, and made during the period from September 5, 1831, to November 14, 1869, I have been enabled to determine the rotation period during that time. This, taken in combination with my discussion of the observations from November 14, 1869, to July 30, 1898 (NATURE, August 4, 1898, and *Monthly Notices* R.A.S., vol. lviii. No. 9), extends the whole interval over which the spot can be pretty certainly identified to nearly 67 years, or 24,435 days, during which the mean rate of rotation was

9h. 55m. 36·2s.

and the total number of rotations

59,071.

My investigation, though quite satisfactory so far as it goes, would be rendered more certain if further observations or drawings could be secured for the period prior to 1869. I should be much obliged, therefore, if any of your readers having such materials in their possession would supply copies, or allow me to have temporary use of the originals. The red spot has varied its appearance so much that it may either appear as a red oval mark, as an elliptic ring, or be practically invisible as at present, though its place may be clearly indicated by a marked hollow in the southern side of the south equatorial belt. Old

drawings of this hollow in the belt will be almost as important, therefore, as delineations of the ellipse itself.

Additional records of this character will serve to exhibit the precise epochs when decided changes occurred in the rate of motion of the spot or its surroundings. The mean rotation period, as mentioned above, seems very well assured from the materials already collected; but it is most desirable to gain more exact information as to the variations, so that the length of the cycle suggested by the observations may be definitely found.

102 City Road, Bristol, November 25. W. F. DENNING.

Galvanometers and Magnetic Dip.

WHILE the variation of magnetic dip in Europe (from about 71° in Aberdeen to 58° in Rome) probably gives little, if any, trouble to users of compasses and portable horizontal galvanometers with pivoted needles, the dip of about 58 *to the south* at the Cape is sufficient to disturb seriously such instruments.

I have seen several galvanometers which were useless until readjusted; these, having been sent out by makers of high reputation, were thought to have received damage on the voyage. I learn that it is a matter of routine in the Post Office to correct all new instruments for dip.

Small pocket compasses are not appreciably affected, because the centre of gravity of the needle is generally well below the point of support, and prismatic compasses escape, probably, on account of the weight of the card.

Instrument makers could easily arrange a small magnetic field in their testing rooms, with a dip to the south of about 60°, in which to adjust instruments intended for the Cape or Australia. A. P. TROTTER.

Cape Town, November 9.

Atropa Belladonna and Birds.

FOR eight years I have had a large plant of Atropa growing here in my garden amongst currants and gooseberries; close by it is a mountain-ash, and at a short distance a large cherry-tree.

Birds, including the blackbird, build in the garden; but although the cherries, currants, gooseberries and raspberries are annually stripped, the Belladonna berries are never touched. The birds are encouraged, and the fruit can be spared.

The Belladonna berries are conspicuous objects from July to November; there are hundreds on my plant every year, long after other fruits have vanished—black, lustrous, luscious-looking—but no bird ever touches them. W. G. S.

Dunstable.

THE ADVANCEMENT OF SCIENCE IN THE ANTARCTIC.

THE President of the Royal Geographical Society has issued an urgent appeal to the Fellows for funds to carry out a National Scientific Expedition to the Antarctic regions on a scale worthy of the traditions of the British nation. He states that a joint committee of the Royal Society and of the Royal Geographical Society has been formed for the purpose of obtaining funds for this purpose, but that "the responsibility of maintaining the credit of the nation in this respect devolves upon the Royal Geographical Society more than on any other body." The Council has accordingly set aside 5000*l*. out of the funds of the Society as a nucleus, to which Mr. Harmsworth, one of the Fellows, has generously added a like sum, and we understand that smaller contributions are rapidly coming in. The cost of a completely equipped expedition will be great, too great we fear for a single Society, even so large and so rapidly growing as the Geographical, to provide, for it is estimated at 100,000*l*. Yet from the point of view of the scientific results sure to be obtained, and the number of the scientific public, the sum is by no means unduly large. Doubtless there will be other Fellows of the Society who can afford and who will not shrink from sharing the position of pre-eminent generosity now occupied by one of their number; but the majority of those interested in the scientific aspects of geography are not wealthy, and they will require assistance from other friends of science. While the vastness of the blank space on the map within the Antarctic circle is sufficient to account for the almost personal feeling of responsibility which Sir Clements Markham and his colleagues acknowledge, there are great gaps in all the natural sciences which only Antarctic research can fill. The physicist, as Prof. Rücker has recently stated, is in the anomalous position of having a theory of terrestrial magnetism far in advance of the facts on which it is based. The meteorologist has two views of atmospheric circulation to consider which can only be reconciled or resolved by observations in the far south. There are geological questions of an interesting kind awaiting solution, including the immensely interesting problem of the former attachment of the southern continents to the land that lies under the south-polar ice-cap. In chemistry uncertainties exist as to the interactions between sea-water and atmospheric gases on the one hand, and marine deposits on the other, which can be studied more fully in the Antarctic than elsewhere. Biology, apart from the certain accumulation of many new species of marine organisms, which might prove a burdensome boon, will find some fascinating problems of environment. The question of the bipolar occurrence of identical species is not as yet overburdened with data for its discussion; but greater interest centres in the life conditions of the vast icy continent—certainly 4,000,000 square miles in area—and absolutely isolated from all the rest of the land of the globe. The climate of most of this land cannot be more rigorous than that of parts of the north polar regions where land-mammals exist; and the biologist, with the exceptional fauna of Australia in view, may reasonably desire to know if there is animal life on Antarctica, and if so what forms it assumes in the unique environment of isolation and low temperature. Even the astronomer may look forward to some return for his contributions to an Antarctic expedition, for where on the land-surface of the globe is there so fine and large a field for the reception and preservation of meteorites? The anthropologist alone can afford, it would appear, to receive the appeal impassively.

All the great scientific societies have long ago expressed their opinion that the time is ripe for a renewal of Antarctic research. The whole newspaper press of the country has applauded the proposal to give effect to this opinion: almost the whole, we ought to say, for a cynically selfish opposition has been offered by one or two of the less influential papers representing the "little Englanders" in science. We hope that all scientific men who have given their approval to the proposed expedition—and who has not?—will ratify that approval, and assist in enabling this country to co-operate with Germany in 1900, and make the last year of the greatest century of scientific advance the world has known the most memorable of all in a field of science whence a great harvest of new facts, but no material return, is to be expected.

Promises and subscriptions are invited to be sent to the credit of the National Antarctic Expedition, to Messrs. Cocks, Biddulph, and Co., Charing Cross, S.W., or to the Royal Geographical Society, 1 Savile Row, W.

THE IMPERIAL UNIVERSITY OF LONDON.

IT is a matter little creditable to English culture that it has required some twenty years of agitation to bring a University for the most important city of the world into the region of practical politics. Within the last fortnight, however, we are glad to know that the machinery of the new Commission has been put in motion, and that inquiries are being made and questions being inquired into of the highest order of importance.

One of these questions has been brought into prominence in a leading article in the *Times* on Saturday last, which shows very clearly that in the opinion of many important persons the University must be launched on no mean scale.

Some of those interested in educational matters suggested some time ago that many of the unused halls of the Imperial Institute could be put to no better service, or one more in harmony with the real intentions of its founders, than their utilisation for some of the purposes of the new University. The Examining Board, hitherto misleadingly called the London University, has always been imperial in its objects, and there is little doubt that when teaching is added to examination the imperial uses will be strengthened.

We shall content ourselves this week in reprinting the *Times* article, which not only indicates very clearly the manner in which Government endowment in the matter of the site may be most economically made, but suggests a somewhat new side of University activity which should not be neglected in these times of commercial competition.

On a future occasion we shall take an opportunity of referring to these and other matters which seem to be among those the consideration of which is necessary to clear the ground for the future labours of the Commission.

The Statutory Commission, appointed under the Act of last Session for the reconstitution of the University of London as a body organised with a strongly developed teaching side, has made a practical beginning with its work during the present week. When that work is accomplished, within the limits imposed by Parliament, it will, no doubt, fail, as every compromise must fail, to realise the ideals of extreme partisans on both sides. Neither those who regarded the old examinational system as perfect and almost sacrosanct, nor those who could see nothing good that did not come out of a teaching institution with a fully-equipped professorial staff, will be altogether satisfied with the change. For ourselves, we cannot doubt that, after unreasonable hesitation and in a somewhat halting and tentative way, a considerable step in advance has been taken for the improvement and expansion of the higher education in the greatest city in the world. But we must not lose sight of the fact that when the Statutory Commission has brought its labours to a close and the results have been laid, in due course, before Parliament, a good deal will remain to be done, partly by legislative action and partly by private effort, before the new system gets a fair start. It is not altogether clear from the Act that the Commissioners have power to decide upon the name of the reconstituted University, though it may be argued as an inference that they can suggest it, and the titles proposed, from time to time, such as the Gresham University and the Albert University, have not met with public acceptance. A point of, perhaps, greater practical importance is that there is no authority to determine where the University is to have its local habitation, and to what extent or in what way teachers "directly appointed by the University," a class expressly mentioned in the schedule to the Act, are to be nominated and provided for. It has been generally assumed that the new University could, for a time at least, be accommodated for the purposes of examination and public meetings in the existing buildings in Burlington Gardens, with the occasional use of rooms lent by some of the chief affiliated colleges. There is reason to believe, however, that this is a misapprehension. We understand that the Government will shortly be under the necessity of resuming the Burlington Gardens site and buildings for the extension of public offices. In that case it would be necessary to furnish the University with new buildings, which at a time when the Treasury will be called upon for an additional grant to the same body for educational objects might not be altogether convenient. The Burlington Gardens property is valued at upwards of 100,000*l.*, but in the hands of the University the rates, taxes, and outgoings are a heavy charge.

There is a magnificent edifice in the best part of London, in which the new University might be housed under conditions worthy of its dignity and aspirations. The stately structure of the Imperial Institute is one of the best examples of modern British architecture. But, though the Institute represents a great conception and has borne excellent fruit, the buildings are far larger than its special work at present requires. It has been suggested that the Imperial Institute, without abandoning any part of its chosen task, might ally itself closely with a kindred institution and, instead of lending its superfluous space for the purposes of casual and miscellaneous exhibitions, might give the enlarged and reformed University a suitable and splendid residence. The privileges and the position of the founders and Fellows and the special interests which the Institute was established to preserve and foster for the advantage of India and the Colonies must, of course, be carefully safeguarded. But the control of the land and buildings by a joint committee, representing the Institute on the one hand and the University on the other, would be full security on this score. It cannot be denied that the Imperial Institute would be an appropriate scene for the ceremonial functions of what might well be called the Imperial University of London. Even at present, the University examines candidates for degrees from the Colonies and India, and, while this duty will be preserved along with the rest of the "external" side of its activity, it will, in all probability, be developed much further when the scheme of which the Statutory Commission is settling the framework has come into full operation. The University, as we have said, is empowered not only to "recognise" competent professors and lecturers in the teaching colleges within the metropolitan area, but also to "appoint" teachers of its own. At the same time it is quite clear that the University is bound not to enter in any way into competition with the colleges recognised as supplying academical teaching for the people of London. To do so would be to depart from the spirit if not the letter of the compromise, on the faith of which the teaching bodies became parties to the scheme of reform. But there is a large sphere of work upon which the existing colleges have not entered and can hardly hope to enter. The establishment of a "Faculty of Commerce"—following the example of Germany—is a development of University work which cannot be neglected in our great centres of trade and industry. In this movement London ought not to be behindhand. Without looking to Government for much more than approval, there are ample resources available, if an appeal is made to the public spirit and liberality of wealthy individuals and of great industrial organisations, for the establishment of professorships of advanced technical study, of applied science in its industrial and commercial aspects, of engineering and electricity, and of many practical branches of economics. These chairs would not compete with the ordinary teaching of the colleges in the abstract and elementary work connected with the sciences in question; but when the student had shown his knowledge of the groundwork he would be able to place himself under the guidance of a selected body of experts and to specialise his studies in preparation for a high degree. The class-rooms and laboratories connected with this part of the work of the University would be for the most part appropriately grouped around the buildings of the Imperial Insitute. There is no reason why degrees given by a Faculty of Commerce and Industry in what might well be called the Imperial University of London should not be eagerly sought for by young men trained in the colleges of Calcutta, Bombay, and Lahore, of Melbourne, Sydney, and Adelaide, of Quebec, Toronto, and Cape Town, as well as by students in the recognised schools of London. At all events, this aspect of the question ought not to be lost sight of either by the Statutory Commission or by the Government.

If, however, the reconstituted University is to take this task in hand, it will be necessary not only to secure the endowment of a number of professorships and lectureships, but to find a fitting place for carrying on the work. The buildings of the Imperial Institute would supply a great part of the acommodation that is needed, but the property includes also some three acres of vacant land which could be turned to account for the erection of laboratories or special class-rooms. It is hardly necessary to mention that the expenditure on the existing buildings has been very large. If the authorities of the Imperial Institute are willing to place the estate at the disposal of the Government, for the purpose of housing the University of London, what seems a very satisfactory arrangement from the point of view of the public might be made. The Prince of Wales and his colleagues are understood to be favourable to such an arrangement, provided, of course, that the special interests with which the Institute is identified are safeguarded.

It may be assumed also that the leading members of the Government look with favour upon the plan, though nothing can be done without the consent of Parliament. The financial details will require to be closely examined. We believe, however, it can be shown that the bargain would be a good one for the State, if the Government were to take over the existing charges on the property of the Imperial Institute, amounting in all to about 5000*l.* a year for rent, taxes, and interest on mortgage. To replace the University of London in a position equal to that in which it stands at present, if it is dispossessed of the Burlington Gardens estate, would probably cost a good deal more, and it would leave no margin, either in space or in money, for the new work which ought to be undertaken if our educational system is to stimulate and nourish our industries and our commerce. It is, in our judgment, most probable that the conspicuous place in the public eye given to the reconstituted University by its installation in the magnificent buildings of the Imperial Institute, especially if it were to be given the designation of the Imperial University of London, would attract substantial support, on a scale not unworthy of the Empire, both in the shape of liberal benefactions and of the enthusiastic and enlightened co-operation of able men. This policy will in no respect interfere with the development of systematic and organised teaching, for which an opportunity will henceforward be afforded, and for the bestowal of degrees founded on such teaching, but will rather complete and strengthen it. At the same time, a higher value and a wider extension will be secured for the external examinations of the University, which opens its doors to competitors from every part of the Empire. It will not be creditable to the British people or to the inhabitants of London, if there is not an energetic attempt to bring what ought to be the centre of the most advanced methods of education up to the level of the work that has been done not only in Berlin and Leipzig, but in many smaller German towns.

NOTES.

The anniversary meeting of the Royal Society took place yesterday as we went to press. An account of the meeting and the annual dinner will be given next week.

M. Depéret has been elected a member of the Paris Academy of Sciences, in the Section of Mineralogy, in succession to the late M. Pomel.

Prof. D'Arcy Thompson, of University College, Dundee, has been appointed to the office of Scientific Member of the Fishery Board for Scotland, vacant by the resignation of Sir John Murray.

Mr. R. T. Baker has been promoted from assistant curator to curator of the Technological Museum, Sydney.

We notice with much regret the announcement of the death of Dr. G. G. Allman, F.R.S., formerly Regius Professor of Natural History in the University of Edinburgh. We regret also to have to announce the death of Mr. Edwin Dunkin, F.R.S., the distinguished astronomer.

The *Southern Cross*, with Mr. Borchgrevink and the other members of the Antarctic expedition under his direction, arrived at Hobart (Tasmania) on Monday. It is expected that the voyage will be continued in a fortnight's time.

It is with great pleasure that we announce the fact that the prize problem of the Naturwissenschaftlich-Mathematischen Facultat of Heidelberg, for a determination of the velocities of various gases and vapours at different temperatures, has been successfully won by Mr. Ernest Stevens, of Brighton, for which he has been awarded the gold medal.

At the last meeting of the Council of the Royal Geographical Society, 112 candidates were elected. This is the largest number elected at any one meeting, and it makes the membership of the Society considerably exceed four thousand.

A violent storm was experienced along the New England coast of the United States on Sunday, and did an immense amount of damage. It is reported that the wind reached a velocity of ninety miles an hour at Block Island.

We learn from the *British Medical Journal* that the monument to Prof. Charcot, which is to stand in front of the Salpêtrière, will be unveiled on Sunday next, December 4, at ten a.m. M. Leygues, Minister of Public Instruction, will preside at the ceremony.

The gypsum boulder, found in the boulder clay of Great Crosby, and described in previous numbers of Nature, has now been finally set up in Islington, Great Crosby. The District Council, advised by Mr. T. Mellard Reade, have had it erected upon a pedestal in the attitude in which it lay embedded in the clay. This was found a difficult thing to do, but the result is most successful, and makes the boulder not only of greater scientific value, but artistically more effective and picturesque.

It is announced in *Science* that the U.S. Board of Ordnance and Fortification has decided to institute an investigation of the possibilities of flying machines for reconnoitreing purposes and as engines of destruction in time of war, and 25,000 dollars of the fund at the disposal of the Board was appropriated for the purpose. The experiments will be carried out under the direction of General A. W. Greely, of the Signal Service, who will have the advantage of the advice of Prof. Langley.

At the meeting of the Society of Public Analysts to be held next Wednesday evening, December 7, an illustrated lecture will be delivered by Mr. A. H. Allen, of Sheffield, on "The use of the micro-spectroscope, and the methods of detecting blood in chemical-legal investigations." Any persons who may be interested in the subject are invited by the Council to attend. Intending visitors, who will not be introduced by members of the Society, are requested to apply for tickets to Mr. E. J. Bevan, Hon. Secretary, 4 New Court, Lincoln's Inn, London, W.C.

The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about 180 dollars (36*l.*), will be made on July 14, 1899. Essays presented for competition may be upon any subject in medicine, but must not have been published. They should be received by the Secretary of the College on or before May 1, 1899.

By the death of Prof. Michele Stefano di Rossi, which recently took place at his home at Rocca di Papa, seismologists have lost from their ranks an enthusiastic worker whose name will long be remembered. By his voluminous writings in the *Bolletini del Vulcanismo Italiano*, of which he was editor, and his "Meteorologica Endogena," di Rossi drew the attention of the people of Italy and the world to the importance of studying the ubiquitous movements of the earth's crust; and there is no doubt that it was in great measure the result of this incentive that we now find in the Italian peninsula the elaborate system which exists for seismological investigations. During his later years failing health prevented his taking any active part in the modern developments of seismology; but it was always a pleasure for him to visit the observatory a few steps from his own door, where with Dr. Cancani he could watch and discuss the work of others. The subject to which he devoted the greatest attention was perhaps tromometry, in connection with which he devised many instruments, and made very many thousands of observations. Di Rossi's tremor-recorders are to be seen in nearly all the Italian observatories; whilst the Rossi-Forel scale, as indicating the intensity of an earthquake disturbance, has found acceptance throughout the world.

The *British Medical Journal* states that the arrangements for providing a school of tropical medicine at the branch hospital of the Seamen's Hospital Society, Victoria and Albert Dock, London, E., are making satisfactory progress. A sub-committee, consisting of Mr. Nairne (chairman), Sir C. Gage Brown, K.C.M.G., Mr. Macnamara, Dr. Lauder Brunton, Dr. Stephen Mackenzie, Dr. Manson, Dr. James L. Maxwell, Mr. Johnson Smith, Mr. William Turner, and Mr. James Cantlie, is now engaged in drawing up a constitution for the school, and defining the curriculum. The new buildings will, it is expected, be completed by October 1, 1899, and it is announced that Mr. Chamberlain intends to preside at a festival dinner to be held during the coming parliamentary session.

Referring to Mr. Chamberlain's scheme of establishing a school of tropical medicine, the *Lancet* questions whether the branch hospital at the Royal Albert Dock is the best nucleus for such a school. After pointing out that a very small number of persons suffering from tropical diseases have been under treatment at the branch hospital, the *Lancet* remarks: "It is intended that laboratories should be equipped at the new school for the purposes of research. But surely that is unnecessary. Laboratories already exist with every requisite appliance for such work on the Victoria Embankment, at Chelsea, and at certain metropolitan medical schools. Here qualified medical men already attend from all parts of the world, such as Uganda, West Africa, Australia, Canada, &c., and diseases of tropical climates—such as malaria, leprosy, plague, cholera, Madura foot, &c.—have especially been made the subjects of original research. A knowledge of bacteriology is essential to colonial practitioners, but we doubt whether anything would be gained by the establishment of new laboratories, as is laid down in the scheme for the new school."

We learn from the Trinidad *Bulletin of Miscellaneous Information* that Dr. Morris, superintendent of the Botanical Department for the Lesser Antilles, will have the control of the following stations: Barbadoes, Grenada, St. Vincent, St. Lucia, Dominica, Montserrat, Antigua, and St. Kitts. The Jamaica, Demerara, and Trinidad stations will at present remain independent, and it is proposed to establish a new station at Tobago, which will be under the control of Trinidad.

At the Meteorological Conference at Munich, in 1891, a Committee was formed for the establishment and direction of stations for special cloud observations, and at the meeting of the International Meteorological Committee at Upsala, in 1894, it was decided that regular observations should be made during at least a year, commencing with May 1896. Dr. Hildebrandsson, director of the Upsala Observatory, has just published the observations made there during that period, consisting of nearly three thousand measurements of heights and velocities, of which 1635 have been made by means of photography. The discussion of the results shows that the annual variation of the mean height of the clouds is very pronounced, with a maximum during the months of June and July, and a minimum during winter. During the summer season the mean height of the cirrus is 8176 metres, and of the cumulus 1685 metres. The heights of the upper and middle level clouds are lower than at the Blue Hill Observatory in Massachusetts, while the lower forms are at nearly the same level; this is probably a natural effect of the difference of position of the two stations. The velocity of the upper clouds is greater than that of the lower, and the velocity of all clouds is greater in winter than in summer.

The *Dublin Journal of Medical Science* for October contains an interesting address delivered at the Congress of the Royal Institute of Public Health, by Dr. J. W. Moore, entitled "Ireland, its Capital and Scenery," in which a trustworthy summary of the climate of Dublin is given, based upon a long series of observations made partly by Dr. Moore himself, and partly collected from other sources. He states that the climate of Dublin is, in the fullest sense, an *insular* one, free from extremes of heat and cold, except on very rare occasions. Since January 1865, the extreme readings of the thermometer in a properly protected screen have been $87^{\circ}\cdot2$, in July 1876, and $13^{\circ}\cdot3$, in December 1882—a range of $73^{\circ}\cdot9$. But these values are very exceptional; the average annual range of mean temperature is not quite 20°, viz. January, $41^{\circ}\cdot1$, and July, $60^{\circ}\cdot3$.

Industries and Iron of November 25 is a special motor-car number. Numerous kinds of motor vehicles are described, and the facts brought together show that automobile locomotion has passed through its first stage of experimentation, and is now emerging into a strictly practical stage of definite manufacture. The extension of this kind of traffic last year appears to have been relatively greater than in the previous year. Apparently but little has been done to improve electrical motor vehicles during the past twelve months. In steam vehicles, on the other hand, the advance has been great; England being at the front in this section of self-propelled locomotion. In the construction of vehicles propelled by means of petroleum spirit motors, the advance is quite as noteworthy from a constructional point of view, for British makers are exporting such vehicles to all parts of the world, as well as keeping their factories fully employed in turning out vehicles for home requirements. In regard to engines taking power from explosive admixtures of the vapours of paraffin oils in conjunction with air, there has been little advance. The difficulty which has yet to be overcome is in regard to the fumes of the gases exhausted from the cylinders. Kerosene has, however, proved a most useful servant when used as fuel for steam generators.

We learn from *Science* that Prof. J. K. Rees, of the Columbia University Observatory, has received recently, from Miss Catherine W. Bruce, of New York City, means for building a special photographic telescope. This instrument will be mounted at Helsingfors, and will be employed by Dr. Donner to make polar trail-plates for Dr. Jacoby, in accordance with the plan suggested by him lately at the Astronomical Conference in Boston. Miss Bruce also sent Prof. Rees funds for carrying on the computing work of the observatory. Dr. H. S. Davis, in his work on the re-reduction of Piazzi's star catalogue, has been generously aided by the same liberal giver.

Mr. A. W. Clayden's model of the world, constructed to illustrate the production of ocean currents by constant winds blowing upon the surface of the oceans, is very well known. A large model of this kind, measuring six feet by four, has been made in aluminium by Messrs. Philip and Sons for Mr. Samuel Hordien, of Sydney, who proposes to present it to a museum in that city. An interesting addition to the model is a simple means by which the artificial monsoons can be made to blow separately upon the water, so that the difference of direction of oceanic movements in the monsoon area during the prevalence of these winds can be exhibited.

In the *Journal de Physique* for November, M. André Broca discusses the use of india-rubber supports for isolating physical apparatus from earth-tremors. He points out that when galvanometers, or other apparatus having movable parts, are supported in this way, the disturbances, so far from being reduced, may in some cases be increased tenfold. This is due to synchronisation of the periods of free oscillation of the supported apparatus with the periods of the disturbances, and this synchronisation is only intensified by the rubber supports. On the other hand, when

the apparatus consist entirely of rigid parts, as in optical experiments, there is no better way of ensuring steadiness than by placing the optic bench on a heavy table whose legs rest on four blocks of india-rubber.

DR. H. F. MOORE, of the United States Fish Commission, is reported by *Science* to have been making a careful examination of the physical conditions of Great Salt Lake, with a view to determine its adaptability to oysters and other salt-water and brackish-water animals. While it is known that the salinity of the open lake is so great as to preclude the possibility of the acclimatisation of useful marine animals, it has been suggested that there are certain bays or arms of the lake, in which rivers discharge, where the density is lowered to a point somewhat less than that of ocean water, and where it may be possible for clams, oysters, crabs, terrapins and such animals to survive and multiply. Dr. Moore has not completed his inquiries, but it may be said that the outlook for an augmentation of the aquatic food resources of this region is not very promising, the amount of fresh water entering the lake being subject to great variation, and the existence of a natural food supply for the introduced species being uncertain.

OWING to the thoroughness of the investigations made on the *Challenger* and other deep-sea explorations, our knowledge of the deposits of ocean depths is, if not more extensive, more coherent and better generalised than that of the more complex and changeable deposits in the shallower coastal waters. Great interest therefore attaches to the systematic exploration of the Irish Sea bottom, now being carried on by the Liverpool Marine Biological Committee, of which an instalment appears in the recent number of the *Proceedings* of the Liverpool Geological Society. Messrs. Herdman and Lomas describe and classify forty-four dredged samples, and discuss some of the general questions raised. Among other things the rottenness of many aragonite shells as contrasted with calcite shells, and the general occurrence of organic remains in a drifted condition, rather than *in situ*, are of special geological interest. The authors remark that "a place may be swarming with life and yet leave no trace of anything capable of being preserved in the fossil state, whereas in other places, barren of living things, banks of drifted and dead shells may be formed, and remain as a permanent deposit on the ocean floor."

AN essay on certain eruptive rocks from the Transvaal, and on other South African rocks, forms the inaugural dissertation submitted by Mr. J. A. Leo Henderson to the University of Leipzig, in order to obtain the degree of Doctor of Philosophy. It is published by Dulau and Co, The rocks to which attention is specially directed are the olivine-free Norites, Gabbros and Pyroxenites of the Transvaal; and it is remarked that the Norites of the Zwaartkoppies range (hitherto termed Gabbros) have mutually intergrown or interlocked rhombic and monoclinic pyroxenes. Attention is also drawn to the occurrence of Anorthoclase rocks of the holocrystalline as well as porphyritic facies. These latter are free from quartz, and therefore correspond to the Syenites, being evidently the link between the Syenitic and Granitic rocks on the one hand, and the Diorites and Diabases on the other. For these holocrystalline and porphyritic types of rock respectively, the author suggests the names of "Hatherlite" and "Pilandite," from the localities (Hatherley and Pilandsberge) where they have been met with. Förster's name of "Pantellerite" applies to the volcanic equivalents of these rocks. The essay is illustrated by five plates.

THE old maxim of "If at first you don't succeed, try, try try again," is a very good one to keep in mind when endeavouring even to produce anything good in the photographic line, Success has at last rewarded the efforts of Mr. J. E. Johnson, who has been experimenting since the year 1886 in the manufacture of half-tone cross-line screens for use in the production of process-engravings. Many of us admire the really beautiful reproductions that are of every-day occurrence in our illustrated publications; but how few are there who inquire into the processes by which such illustrations are made possible. If our readers are interested in this kind of work, let them take an illustration by one of these processes, and apply to it a small magnifying glass and examine the texture, so to speak, of the detail. Several excellent illustrations are reproduced in *The Process Photogram* for November, and are accompanied by the first of a series of articles which describe the British half-tone screen: the word "British" is here used because, until quite recently, the whole of the manufacture of these screens was in the hands of Mr. Max Levy, of Philadelphia. The screens which Mr. Johnston has succeeded in making indicate an important departure in British manufacture, and they are capable of doing very fine work. A great amount of money has already been unsuccessfully spent by British, German and French machine-rulers to produce satisfactory half-tone screens, and it is satisfactory to be able to record the fact that a British firm has thoroughly solved the problem. The above-mentioned article, and those that will follow it, give some technical particulars of these new screens, and will be found very interesting. Incidentally we may mention that the *Photogram* for November is full of interesting matter and the usual well-reproduced illustrations.

AN illustrated paper on the ruins of Xkichmook, Yucatan, prepared by Mr. E. H. Thompson, has been published by the Field Columbian Museum, under the auspices of which the archaeological investigations described were carried on. Excavations were made at many points, walls were uncovered and traced, cisterns were cleaned out, graves were examined, and many objects of art were procured. Pottery and flaked stone implements were plentiful, but polished implements and specimens of sculpture were exceedingly rare. Mr. Thompson remarks that at Xkichmook and elsewhere in Yucatan he has never found a single obsidian implement, except slender blades that probably served as knife blades. At Xkichmook he found more plentiful traces of the ancient fabrication of flint implements than in any other group of ruins. With the exception of a celt fragment made of nephrite, not a single polished stone implement was found.

A CATALOGUE of more than two hundred pages, containing particulars and prices of books and papers offered for sale, has just been issued by Messrs. Dulau and Co.

A POPULAR account of Etna and some of its eruptions, illustrated by several reproductions of photographs, and a contour map of the central crater, is contained in a brochure by Prof. Albin Belar, just published at Laibach. The description has been reprinted from the *Laibacher Zeitung*.

DR. R. V. WETTSTEIN has reprinted, from the *Transactions* of the (German) Bohemian Association for Natural Science and Medicine, an interesting paper on the means of protection of the flowers of geophilous plants, *i.e.* those in which the flowering branches are formed beneath the surface of the soil.

THE first of a series of papers on new or imperfectly known species of earthworms collected from various parts of the Japanese empire is contributed to *Annotationes Zoologicae Japonenses* (October 10) by Prof. Seitaro Goto and Mr. Shinkichi Hatai.

MESSRS. SAMPSON LOW, MARSTON, & CO. have published an English edition of the very interesting "New Astronomy," by Prof. David P. Todd, recently reviewed in NATURE

(vol. lviii. p. 173). The volume is profusely illustrated, and contains descriptions of a number of ingenious devices to illustrate astronomical phenomena.

A VOLUME entitled "Notes on Water Supply," containing, among other matters, references, tables, notes, memoranda, and detailed advertisements in relation to water-works engineering, has been prepared by Mr. J. T. Rodda, and is published by Messrs. King, Sell, and Railton, Ltd. The work will be found useful in indicating what water-works appliances are in the market, and their usefulness in modern distribution of water supply.

TWO publications of the U.S. Department of Agriculture (Division of Biological Survey) have reached us:—"Life-zones and Crop-zones of the United States," by C. H. Merriam, the Chief of the Survey; and "the Geographical Distribution of Cereals in North America," by C. S. Plumb. Both are illustrated by a coloured map of the States (including Cuba), showing the delimitation of the "Life-zones"—the Boreal, the Transition, the Upper Austral, the Lower Austral, the Gulf strip of the Lower Austral, and the Tropical zones.

MR. BERNARD QUARITCH announces that the first volume of the work on the zoology of Egypt, with which Dr. John Anderson, F.R.S., has been engaged for some time, is now ready. As the result of five years devoted to collecting, 1500 specimens of reptiles and batrachians were brought together, of which more than 1400 were permanently preserved. The formation of this collection was the first step towards the preparation of the volume on "Reptilia and Batrachia" now published; for these groups were so poorly represented in the museums of this country and of Europe that it would have been impossible to have derived from them any just conception of the extent of these constituents of the Egyptian fauna. Only 100 copies of Dr. Anderson's work have been printed. Purchasers of the first volume, now available, do not bind themselves to take further volumes.

SINCE the discovery by Graham, in 1856, of the remarkable property of palladium of absorbing hydrogen, many researches have been carried out with the object of throwing some light upon the relations existing between the metal and the gas, and with the result that there are nearly as many different views as experimenters. From the theoretical discussion, there would at first sight appear to be no difficulty in distinguishing experimentally between the alloy or solid solution hypothesis and the view that a definite compound, a hydride, is formed. The pressure-concentration curve, in particular, would be expected to decide at once between these two views. But the application of this method is rendered difficult, if not useless, by the fact that the shape of the curve varies greatly with temperature. At 100° C., for instance, the horizontal portion required by the hypothesis of Pd_2H being present is well marked (Troost and Hautefeuille), but at 200° C. no trace of this is present. Of the electrical methods tried, the most recent is that of Dr. J. Shields (*Proc. Roy. Soc. Edin.*, vol. xxii. 169), who examined the electro-motive force of the concentration cell, palladium-hydrogen (weak) / dilute sulphuric acid / palladium-hydrogen (strong), where the concentrations of the hydrogen were weak and strong at the two electrodes. The electro-motive force of the cell was found to be zero, or nearly so. This is opposed to the solid solution hypothesis, and agrees better with the view that a definite chemical compound is formed.

THE additions to the Zoological Society's Gardens during the past week include a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Mrs. M. Riach; a Guinea Baboon (*Cynocephalus sphinx*, ♂) from Africa, presented by Captain Armitage; a Smith's Dwarf Lemur (*Microcebus smithi*) from Madagascar; a Crab eating Opossum (*Didelphys cancrivorus*) from Tropical America, two One-wattled Cassowaries (*Casuarius uniappendiculatus*) from New Guinea, a Common Rhea (*Rhea americana*) from the Argentine Republic, deposited; a Tesselated Snake (*Tropidonotus tesselatus*) European, purchased; a Yak (*Poephagus grunniens*, ♀), a Llama (*Lama peruana*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN DECEMBER:—

December 2. Venus at maximum diameter 63″·4.
3. Mercury at greatest E. elongation (21° 3′), and visible after sunset.
5. 20h. 2m. to 21h. 11m. Occultation of 55 Leonis (mag. 6) by the moon.
6. 12h. 54m. to 13h. 24m. Occultation of ϵ Leonis (mag. 5·1) by the moon.
10. 8h. 42m. Minimum of Algol (β Persei).
10-12. Meteoric shower from Gemini (Radiant 108° + 33°.)
13. Neptune 52′ N. of ζ Tauri.
13. 5h. 30m. Minimum of Algol (β Persei).
14. 19h. Neptune in opposition to the sun.
15. Mars. Apparent diameter 12″·6. Illuminated portion of disc 0·951.
15. Jupiter. Apparent diameter 30″·2.
19. 3h. 0m. to 3h. 46m. Occultation of κ Piscium (mag. 5) by the moon.
23. 9h. 4m. to 10h. 11m. Occultation of 47 Arietis (mag. 5·9) by the moon.
27. 11h. 38m. Middle of a total eclipse of the moon. The total phase endures from 10h. 57m. to 12h. 27m., a period of about $1\frac{1}{2}$ hours. The magnitude of the eclipse will be = 1·383, the moon's diameter being considered = 1.
29. 10h. 1m. to 11h. 16m. Occultation of ζ Cancri (mag. 5) by the moon.

A NEW COMET.—Two telegrams from Kiel announce observations of a new comet discovered by Chase.

The first from Newhaven, dated November 24, gives the position of this object on November 14, 12h. 38m. Newhaven time, as R.A. 10h. 7m. 4s., and Declination + 22° 55′; the motion being + 1m. 36s. in R.A., and + 4′ in Declination. It was described as "faint."

The second telegram, dated November 25, gives an observation made by Coddington on November 23, at 17h. Lick time. The Right Ascension then was 10h. 21m. 48s., and the Declination + 23° 37′

NOVEMBER METEORS.—The observations of the November meteors have been very much hindered owing to the extremely cloudy weather that has prevailed nearly everywhere. There seems, however, to have been greater success with the Leonids on the night of the 13-14th of last month. M. Janssen (*Comptes rendus*, November 21) eliminated cloudy weather by going up about 200 metres in a balloon at two o'clock on the morning of the 14th. M. Hausky, who was with the party, observed the constellation of Leo, while the others took different portions of the sky. Between 2h. 45m. to 4h. 30m., however, only 25 Leonids were recorded. It is stated that next year ascensions on a large scale will be organised. At the Observatory of Lyons the weather was very favourable, and some useful observations were made by M. André and Guillaume. The former observer, in a watch lasting from 8h. to 12h. 15m., observed 34 meteors, 22 of which he estimated as Leonids. M. Guillaume, from 13h. 4m. to 16h. 5m. saw no less than 134 in three hours, which is about 45 meteors an hour. The radiant point he deduced was 155° + 18°.

PARALLAX OF η PEGASI.—In this column for September 10 last, we gave a brief note concerning the determinations of the velocities in the line of sight of the variable η Pegasi, made by Prof. W. W. Campbell. Concerning the parallax of this star, Mr. C. E. Stromeyer writes to us and suggests that "photographs or micrometric measurements of the position of this star should be taken at periods when its velocity in the line of sight

is a maximum or a minimum; as, for instance, in May 1896, July 1897, August 1898, September 1899, &c. Should it then be found that the angular displacement is less than one-tenth of a second, we have at least sufficient data to be able to say that this star has a parallax of less than one-twentieth of a second. Possibly photographs or micrometric measurements are available in some observatories."

THE NEW PLANET WITT DQ.—The discovery of the little planet Witt DQ is of such importance that it behoves astronomers now to seek out a name for it which will be appropriate. The minor planet family, which now numbers some hundreds, has practically monopolised most of the gods and goddesses, so that a suitable choice in its nomenclature is not an easy matter. Prof. S. C. Chandler, with all due regard to the right of the discoverer, both by courtesy and the precedent of custom, of suggesting a name, proposes Pluto, which he thinks is appropriate in many ways. The other sons of Saturn have all worthily been assigned to major and minor planets; but Pluto has been, up to the present, omitted. Moreover, as Prof. Chandler says, "there is a certain fitness in the appellation arising from its faintness or invisibility on ordinary occasions. Pluto, under his older name, Hades, was the 'invisible' or 'unknown,' the god of darkness. This invisibility, he removes, with the helmet forged for his concealment by Vulcan, when he comes to perihelion opposition, shining then as a comparatively bright star, perhaps visible to the naked eye. This helmet, by the way, could serve as his conventional planetary symbol, if one is desired."

SCIENCE IN EDUCATION.[1]

WHEN the history of education during the nineteenth century comes to be written, one of its most striking features will be presented by the rise and growth of science in the general educational arrangements of every civilised country. At the beginning of the century our schools and colleges were still following, with comparatively little change, the methods and subjects of tuition that had been in use from the time of the Middle Ages. But the extraordinary development of the physical and natural sciences, which has done so much to alter the ordinary conditions of life, has powerfully affected also our system of public instruction. The mediaeval circle of studies has been widely recognised not to supply all the mental training needed in the ampler range of modern requirement. Science has, step by step, gained a footing in the strongholds of the older learning, Not without vehement struggle, however, has she been able to intrench herself there. Even now, although her ultimate victory is assured, the warfare is by no means at an end. The jealousy of the older régime and the strenuous, if sometimes blatant, belligerency of the reformers have not yet been pacified; and, from time to time, within our public schools and universities, there may still be heard the growls of opposition and the shouts of conflict. But these sounds are growing fainter. Even the most conservative don hardly ventures nowadays openly to denounce science and all her works. Grudgingly, it may be, but yet perforce, he has to admit the teaching of modern science to a place among the subjects which the university embraces, and in which it grants degrees. In our public schools a "modern side" has been introduced, and even on the classical side an increasing share of the curriculum is devoted to oral and practical teaching in science. New colleges have been founded in the more important centres of population, for the purpose, more particularly, of enabling the community to obtain a thorough education in modern science.

The mainspring of this remarkable educational revolution has, doubtless, been the earnest conviction that the older learning was no longer adequate in the changed and changing conditions of our time; that vast new fields of knowledge, opened up by the increased study of nature, ought to be included in any scheme of instruction intended to fit men for the struggle of modern life, and that in this newer knowledge much might be found to minister to the highest ends of education. Nevertheless, it must be admitted that utilitarian considerations have not been wholly absent from the minds of the reformers. Science has many and far-reaching practical applications. It has called into existence many new trades and professions, and has greatly modified many of those of older date. In a thousand varied ways it has come into the ordinary affairs of every-day life. Its cultivation has brought innumerable material benefits; its neglect would obviously entail many serious industrial disadvantages, and could not fail to leave us behind in the commercial progress of the nations of the globe.

So much have these considerations pressed upon the attention of the public in recent years that, besides all the other educational machinery to which I have referred, technical schools have been established in many towns for the purpose of teaching the theory as well as the practice of various arts and industries, and making artisans understand the nature of the processes with which their trades are concerned.

That this educational transformation, which has been advancing during the century, has resulted in great benefit to the community at large can hardly be denied. Besides the obvious material gains, there has been a widening of the whole range and method of our teaching; the old subjects are better, because more scientifically taught, and the new subjects enlist the attention and sympathy of large classes of pupils whom the earlier studies only languidly interested. Nevertheless, it is incumbent on those who have advocated and carried out this change to ask themselves whether it has brought with it no drawbacks. They may be sure that no such extensive reform could possibly be accomplished without defects appearing somewhere. And it is well to look these defects in the face and, as far as may be possible, remove them. In considering how I might best discharge the duty with which I have been honoured of addressing the students of Mason College this evening, I have thought that it might not be inappropriate if, as a representative of science, I were to venture to point out some of the drawbacks as well as the advantages of the position which science has attained in our educational system.

At the outset no impartial onlooker can fail to notice that the natural reaction against the dominance of the older learning has tended to induce an undervaluing of the benefits which that learning afforded and can still bestow. In this College, indeed, and in other institutions more specially designed for instruction in science, provision has also been made for the teaching of Latin, Greek, and the more important modern languages and literatures. But in such institutions, these subjects usually hold only a subordinate place. It can hardly be denied that generally throughout the country, even although the literary side of education still maintains its pre-eminence in our public schools and universities, it is losing ground, and that every year it occupies less of the attention of students of science. The range of studies which the science examinations demand is always widening, while the academic period within which these studies must be crowded undergoes no extension. Those students, therefore, who, whether from necessity or choice, have taken their college education in science, naturally experience no little difficulty in finding time for the absolutely essential subjects required for their degrees. Well may they declare that it is hopeless for them to attempt to engage in anything more, and especially in anything that will not tell directly on their places in the final class-lists. With the best will in the world, and with even, sometimes, a bent for literary pursuits, they may believe themselves compelled to devote their whole time and energies to the multifarious exactions of their science curriculum.

Such a result of our latest reformation in education may be unavoidable, but it is surely matter for regret. A training in science and scientific methods, admirable as it is in so many ways, fails to supply those humanising influences which the older learning can so well impart. For the moral stimulus that comes from an association with all that is noblest and best in the literatures of the past, for the culture and taste that spring from prolonged contact with the highest models of literary expression, for the widening of our sympathies and the vivifying of our imagination by the study of history, the teaching of science has no equivalents.

Men who have completed their formal education with little or no help from the older learning may be pardoned should they be apt to despise such help and to believe that they can very well dispense with it in the race of life. My first earnest advice to the science students of this College is, not to entertain this belief and to refuse to act on it. Be assured that, in your future career, whatever it may be, you will find in literature a source of solace and refreshment, of strength and encouragement, such as no department of science can give you. There will come

[1] An address to the students of Mason University College, Birmingham, at the opening of the session, October 4, by Sir Archibald Geikie, D.C.L., F.R.S.

times, even to the most enthusiastic among you, when scientific work, in spite of its absorbing interest, grows to be a weariness. At such times as these you will appreciate the value of the literary culture you may have received at school or college. Cherish the literary tastes you have acquired, and devote yourselves sedulously to the further cultivation of them during such intervals of leisure as you may be able to secure.

Over and above the pleasure which communion with the best books will bring with it, two reasons of a more utilitarian kind may be given to science students why they should seek this communion. Men who have been too exclusively trained in science, or are too much absorbed in its pursuit, are not always the most agreeable members of society. They are apt to be somewhat angular and professional, contributing little that is interesting to general conversation, save when they get a chance of introducing their own science and its doings. Perhaps the greatest bore I ever met was a man of science, whose mind and training were so wholly mathematical and physical that he seemed unable to look at the simplest subject save in its physical relations, about which he would discourse till he had long exhausted the patience of the auditor whom he detained. There is no more efficacious remedy for this tendency to what is popularly known as "shop" than the breadth and culture of mind that spring from wide reading in ancient and modern literature.

The other reason for the advice I offer you is one of which you will hardly, perhaps, appreciate the full force in the present stage of your career. One result of the comparative neglect of the literary side of education by many men of science is conspicuously seen in their literary style. It is true that in our time we have had some eminent scientific workers, who have also been masters of nervous and eloquent English. But it is not less true that the literature of science is burdened with a vast mass of slipshod, ungrammatical and clumsy writing, wherein sometimes even the meaning of the authors is left in doubt. Let me impress upon you the obvious duty of not increasing this unwieldy burden. Study the best masters of style, and when once you have made up your minds what you want to say, try to express it in the simplest, clearest, and most graceful language you can find.

Remember that, while education is the drawing out and cultivation of all the powers of the mind, no system has yet been devised that will by itself develop with equal success every one of these powers. The system under which we have been trained may have done as much for us as it can do. Each of us is thereafter left to supplement its deficiencies by self-culture. And in the ordinary science-instruction of the time one of the most obvious of these inevitable deficiencies is the undue limitation or neglect of the literary side of education.

But in the science-instruction itself there are dangers regarding which we cannot be too watchful. In this College and in all the other well-organised scientific institutions of the country, the principles of science are taught orally and experimentally. Every branch of knowledge is expounded in its bearings on other branches. Its theory is held up as the first great aim of instruction, and its practical applications are made subsequent and subordinate. Divisions of science are taught here which may have few practical applications, but which are necessary for a comprehensive survey of the whole circle of scientific truth. Now, you may possibly have heard, and in the midst of a busy industrial community you are not unlikely to hear, remarks made in criticism of this system or method of tuition. The importance of scientific training will be frankly acknowledged and even insisted upon, but you will sometimes hear this admission coupled with the proviso that the science must be of a practical kind; must, in short, be just such and no other, as will fit young men to turn it to practical use in the manufactures or industries to which they may be summoned. The critics who make this limitation boast that they are practical men, and that in their opinion theory is useless or worse for the main purposes for which they would encourage and support a great scientific school.

Now I am quite sure that those science students who have passed even a single session in Mason College can see for themselves the utter fallacy of such statements and the injury that would be done to the practical usefulness of this institution and to the general progress of the industrial applications of science if such short-sighted views were ever carried into effect. There can be no thorough, adequate, and effective training in science unless it be based on a comprehensive study of facts and principles, altogether apart from any economic uses to which they may be put. Science must be pursued for her own sake, in the first instance, and without reference to any pecuniary benefits she may be able to confer. We never can tell when the most theoretical part of pure science may be capable of being turned to the most important practical uses. Who could have surmised, for instance, that in the early tentative experiments of Volta, Galvani, and others last century lay the germ of the modern world-grasping electric telegraph? Or when Wedgwood, at the beginning of this century, copied paintings by the agency of light upon nitrate of silver, who could have foretold that he was laying the foundations of the marvellous art of photography?

There can be no more pernicious doctrine than that which would measure the commercial value of science by its immediate practical usefulness, and would restrict its place in education to those only of its sub-divisions which may be of service to the industries of the present time. Such a curtailed method of instruction is not education in the true sense of the term. It is only a kind of cramming for a specific purpose, and the knowledge which it imparts, being one-sided and imperfect, is of little value beyond its own limited range. I by no means wish to undervalue the importance of technical instruction. By all means let our artisans know as much as can be taught them regarding the nature and laws of the scientific processes in which they are engaged. But it is not by mere technical instruction that we shall maintain and extend the industrial and commercial greatness of the country. If we are not only to hold our own, but to widen the boundaries of applied science, to perfect our manufactures, and to bring new departments of nature into the service of man, it is by broad, thorough, untrammelled scientific research that our success must be achieved.

When, therefore, you are asked to explain of what practical use are some of the branches of science in which you have been trained, do not lose patience with your questioner, and answer him as you think such a Philistine deserves to be answered. Give him a few illustrations of the thousands of ways in which science, that might have been stigmatised by him as merely abstract and theoretical, has yet been made to minister to the practical needs of humanity. Above all, urge him to attend some of the classes of Mason College, where he will learn, in the most effectual manner, the intimate connection between theory and practice. If he chance to be wealthy, the experiment may possibly open his eyes to the more urgent needs of the institution, and induce him to contribute liberally towards their satisfaction.

Among the advantages and privileges of your life at college there is one, the full significance and value of which you will better appreciate in later years. You have here an opportunity of acquiring a wide general view of the whole range of scientific thought and method. If you proceed to a science degree you are required to lay a broad foundation of acquaintance with the physical and biological sciences. You are thus brought into contact with the subjects of each great department of natural knowledge, and you learn enough regarding them to enable you to understand their scope and to sympathise with the workers who are engaged upon them. But when your academical career is ended, no such chance of wide general training is ever likely to be yours again. You will be dragged into the whirl of life, where you will probably find little time or opportunity to travel much beyond the sphere of employment to which you may have been called. Make the most, therefore, of the advantages which in this respect you meet with here. Try to ensure that your acquaintance with each branch of science embraced in your circle of studies shall be as full and accurate as lies in your power to make it. Even in departments outside the bounds of your own tastes and ultimate requirements, do not neglect the means provided for your gaining some knowledge of them. I urge this duty, not because its diligent discharge will obviously tell in your examinations, but because it will give you that scientific culture which, while enabling you to appreciate and enjoy the successive advances of other sciences than that which you may select for special cultivation, will at the same time increase your general usefulness and aid you in your own researches.

The days of Admirable Crichtons are long since past. So rapid and general is the onward march of science that not only can no man keep pace with it in every direction, but it has become almost hopelessly impossible to remain abreast of the progress in each of the several sub-divisions of even a single

science. We are entering more and more upon the age of specialists. It grows increasingly difficult for the specialists, even in kindred sciences, to remain in touch with each other. When you find yourselves fairly launched into the vortex of life you will look back with infinite satisfaction to the time when you were enabled to lay a broad and solid platform of general acquirement within the walls of this College.

Perhaps the most remarkable defect in the older or literary methods of education was the neglect of the faculty of observation. For the training of the other mental faculties ample provision was made, but for this, one of the most important of the whole, no care was taken. If a boy was naturally observant, he was left to cultivate the use of his eyes as he best might; if he was not observant, nothing was done to improve him in this respect, unless it were, here and there, by the influence of such an intelligent teacher as is described in Mrs. Barbauld's famous story of "Eyes and No Eyes." Even when science began to be introduced into our schools, it was still taught in the old or literary fashion. Lectures and lessons were given by masters who got up their information from books, but had no practical knowledge of the subjects they taught. Class-books were written by men equally destitute of a personal acquaintance with any department of science. The lessons were learnt by rote, and not infrequently afforded opportunities rather for frolic than for instruction. Happily this state of things, though not quite extinct, is rapidly passing away. Practical instruction is everywhere coming into use, while the old-fashioned cut-and-dry lesson-book is giving way to the laboratory, the field-excursion, and the school-museum.

It is mainly through the eyes that we gain our knowledge and appreciation of the world in which we live. But we are not all equally endowed with the gift of intelligent vision. On the contrary, in no respect, perhaps, do we differ more from each other than in our powers of observation. Obviously, a man who has a quick eye to note what passes around him must, in the ordinary affairs of life, stand at a considerable advantage over another man who moves unobservantly on his course. We cannot create an observing faculty any more than we can create a memory, but we may do much to develop both. This is a feature in education of much more practical and national importance than might be supposed. I suspect that it lies closer than might be imagined to the success of our commercial relations abroad. Our prevalent system of instruction has for generations past done nothing to cultivate the habit of observation, and has thus undoubtedly left us at a disadvantage in comparison with nations that have adopted methods of tuition wherein the observing faculty is regularly trained. With our world-wide commerce we have gone on supplying to foreign countries the same manufactured goods for which our fathers found markets in all quarters of the globe. Our traders, however, now find themselves in competition with traders from other nations who have been trained to better use of their powers of observation, and who, taking careful note of the gradually changing tastes and requirements of the races which they visit, have been quick to report these changes and to take means for meeting them. Thus, in our own centres of trade, we find ourselves in danger of being displaced by rivals with sharper eyes and greater powers of adaptation.

It is the special function of science to cultivate this faculty of observation. Here in Mason College, from the very beginning of your scientific studies you have been taught to use your eyes, to watch the phenomena that appear and disappear around you, to note the sequence and relation of these phenomena, and thus, as it were, to enter beneath the surface into the very soul of things. You cannot, however, have failed to remark among your fellow-students great inequalities in their powers of observation, and great differences in the development of these powers under the very same system of instruction. And you may have noticed that, speaking generally, those class-mates who have shown the best observing faculty have taken foremost places among their fellows. It is not a question of mere brain power. A man may possess a colossal intellect, while his faculty of observation may be of the feeblest kind. One of the greatest mathematicians of this century who, full of honours, recently passed away from us, had so little cognisance of his surroundings, that many ludicrous stories are told of his child-like mistakes as to place and time.

The continued development of the faculty of prompt and accurate observation is a task on which you cannot bestow too much attention. Your education here must already have taught you its value. In your future career the use you make of this faculty may determine your success or your failure. But not only have your studies in this College trained your observing powers, they have at the same time greatly widened the range of your mental vision by the variety of objects which you have been compelled to look at and examine. The same methods which have been so full of benefit to you here can be continued by you in after life. And be assured that in maintaining them in active use you will take effective means for securing success in the careers you may choose to follow.

But above and beyond the prospect of any material success there is a higher motive which will doubtless impel you. The education of your observing faculty has been carried on during your introduction to new realms of knowledge. The whole domain of nature has been spread out before you. You have been taught to observe thousands of objects and processes of which, common though they may be, you had previously taken no note. Henceforth, wherever you may go, you cannot wander with ignorant or unobservant eyes. Land and sea and sky, bird and beast and flower now awaken in you a new interest, for you have learned lessons from them that have profoundly impressed you, and you have discovered meanings in them of which you had never dreamed. You have been permitted to pass within the veil of nature, and to perceive some of the inner mechanism of this world.

Thus, your training in science has not only taught you to use your eyes, but to use them intelligently, and in such a way as to see much more in the world around you than is visible to the uninstructed man. This widened perception might be illustrated from any department of natural science. Let me take, by way of example, the relation of the student of science towards the features and charms of landscape. It may be said that no training is needed to comprehend these beauties; that the man in the street, the holiday maker from town, is just as competent as the man of science to appreciate them, and may get quite as much pleasure out of them. We need not stop to discuss the relative amounts of enjoyment which different orders of spectators may derive from scenery; but obviously the student of science has one great advantage in this matter. Not only can he enjoy to the full all the outward charms which appeal to the ordinary eye, but he sees in the features of the landscape new charms and interests which the ordinary untrained eye cannot see. Your accomplished Professor of Geology has taught you the significance of the outer lineaments of the land. While under his guidance you have traced with delight the varied features of the lovely landscapes of the Midlands, your eyes have been trained to mark their connection with each other, and their respective places in the ordered symmetry of the whole scene. You perceive why there is here a height and there a hollow; you note what has given the ridges and vales their dominant forms and directions; you detect the causes that have spread out a meadow in one place and raised up a hill in another.

Above and beyond all questions as to the connection and origin of its several parts, the landscape appeals vividly to your imagination. You know that it has not always worn the aspect which it presents to-day. You have observed in these ridges proofs that the sea once covered their site. You have seen the remains of long extinct shells, fishes, and reptiles that have been disinterred from the mud and silt left behind by the vanished waters. You have found evidence that not once only, but again and again, after vast lapses of time and many successive revolutions, the land has sunk beneath the ocean and has once more emerged. You have been shown traces of underground commotion, and you can point to places where, over central England, volcanoes were once active. You have learnt that the various elements of the landscape have thus been gradually put together during successive ages, and that the slow processes, whereby the characteristic forms of the ground have been carved out, are still in progress under your eye.

While, therefore, you are keenly alive to the present beauty of the scene, it speaks to you, at every turn, of the past. Each feature recalls some incident in the strange primeval history that has been transacted here. The succession of contrasts between what is now and what has been fills you with wonder and delight. You feel as if a new sense had been given to you, and that with its aid your appreciation of scenery has been enlarged and deepened to a marvellous degree.

And so too is it with your relation to all the other departments of nature. The movements of the clouds, the fall of

rain, the flow of brook and river, the changes of the seasons, the succession of calm and storm, do not pass before your eyes now as they once did While they minister to the joy of life, they speak to you of that all-embracing system of process and law that governs the world. The wayside flower is no longer to your eyes merely a thing of beauty. You have found it to be that and far more—an exquisite organism in which the several parts are admirably designed to promote the growth of the plant and to perpetuate the life of the species. Every insect and bird is now to you an embodiment of the mystery of life. The forces of nature, once so dark and so dreaded, are now seen by you to be intelligible, orderly and capable of adaptation to the purposes of man. In the physical and chemical laboratories you have been brought into personal contact with these forces, and have learnt to direct their operations, as you have watched the manifold effects of energy on the infinite varieties of matter.

When you have completed your course of study and leave this College, crowned, I hope, with academic distinction, there will be your future career in life to choose and follow. A small number among you may, perhaps, be so circumstanced as to be able to devote yourselves entirely to original scientific research, selecting such branches of inquiry as may have specially interested you here, and giving up your whole time and energy to investigation. A much larger number will, no doubt, enter professions where a scientific training can be turned to practical account, and you may become engineers, chemists, or medical men. But in the struggle for existence, which every year grows keener amongst us, these professions are more and more crowded, so that a large proportion of your ranks may not succeed in finding places there, and may in the end be pushed into walks in life where there may be little or no opportunity for making much practical use of the knowledge in science which you have gained here. To those who may ultimately be thus situated it will always be of advantage to have had the mental training given in this Institution, and it will probably be your own fault if, even under unfavourable conditions, you do not find, from time to time, chances of turning your scientfic acquirements to account. Your indebtedness to your professors demands that you shall make the effort, and, for the credit of the College, you are bound to do your best.

Among the mental habits which your education in science has helped to foster, there are a few which I would specially commend to your attention as worthy of your most sedulous care all through life.

In the first place, I would put Accuracy. You have learnt in the laboratory how absolutely essential this condition is for scientific investigation. We are all supposed to make the ascertainment of the truth our chief aim, but we do not all take the same trouble to attain it. Accuracy involves labour, and every man is not gifted with an infinite capacity for taking pains. Inexactness of observation is sure sooner or later to be detected, and to be visited on the head of the man who commits it. If his observations are incorrect, the conclusions he has drawn from them may be vitiated. Thus all the toil he has endured in a research may be rendered of no avail, and the reputation he might have gained is not only lost but replaced by discredit. It is quite true that absolute accuracy is often unattainable; you can only approach it. But the greater the exertion you make to reach it, the greater will be the success of your investigations. The effort after accuracy will be transferred from your scientific work to your every-day life and become a habit of mind, advantageous both to yourselves and to society at large.

In the next place, I would set Thoroughness, which is closely akin to accuracy. Again, your training here has shown you how needful it is in scientific research to adopt thorough and exhaustive methods of procedure. The conditions to be taken into account are so numerous and complex, the possible combinations so manifold, before a satisfactory conclusion can be reached. A laborious collection of facts must be made. Each supposed fact must be sifted out and weighed. The evidence must be gone over again and yet again, each link in its chain being scrupulously tested. The deduction to which the evidence may seem to point must be closely and impartially scrutinised, every other conceivable explanation of the facts being frankly and fully considered. Obviously the man whose education has inured him to the cultivation of a mental habit of this kind is admirably equipped for success in any walk in life which he may be called upon to enter. The accuracy and thoroughness which you have learnt to appreciate and practise at College must never be dropped in later years. Carry them with you as watchwords, and make them characteristic of all your undertakings.

In the third place, we may take Breadth. At the outset of your scientific education you were doubtless profoundly impressed by the multiplicity of detail which met your eye in every department of natural knowledge. When you entered upon the study of one of these departments, you felt, perhaps, almost overpowered and bewildered by the vast mass of facts with which you had to make acquaintance. And yet as your training advanced, you gradually came to see that the infinite variety of phenomena could all be marshalled, according to definite laws, into groups and series. You were led to look beyond the details to the great principles that underlie them and bind them into a harmonious and organic whole. With the help of a guiding system of classification, you were able to see the connection between the separate facts, to arrange them according to their mutual relations, and thus to ascend to the great general laws under which the material world has been constructed. With all attainable thoroughness in the mastery of detail, you have been taught to combine a breadth of treatment which enables you to find and keep a leading clue even through the midst of what might seem a tangled web of confusion. There are some men who cannot see the wood for the trees, and who consequently can never attain great success in scientific investigation. Let it be your aim to master fully the details of the tree, and yet to maintain such a breadth of vision as will enable you to embrace the whole forest within your ken. I need not enlarge on the practical value of this mental habit in every-day life, nor point out the excellent manner in which a scientific education tends to develop it.

In the fourth place, I would inculcate the habit of wide Reading in scientific literature. Although the progress of science is now too rapid for any man to keep pace with the advance of all its departments, you should try to hold yourselves in touch with at least the main results arrived at in other branches than your own; while, in that branch itself, it should be your constant aim to watch every onward step that is taken by others, and not to fall behind the van. This task you will find to be no light one. Even were it confined to a survey of the march of science in your own country, it would be arduous enough to engage much of your time. But science belongs to no country, and continues its onward advance all over the globe. If you would keep yourselves informed regarding this progress in other countries, as you are bound to do if you would not willingly be left behind, you will need to follow the scientific literature of those countries. You must be able to read at least French and German. You will find in these languages a vast amount of scientific work relating to your own department, and to this accumulated pile of published material the journals of every month continue to add. In many ways it is a misfortune that the literature of science increases so fast; but we must take the evil with the good. Practice will eventually enable you to form a shrewd judgment as to which authors or papers you may skip without serious danger of losing any valuable fact or useful suggestion.

In the fifth place, let me plead for the virtue of Patience. In a scientific career we encounter two dangers, for the avoidance of which patience is our best support and guide. When life is young and enthusiasm is boundless; when from the details which we may have laboriously gathered together we seem to catch sight of some new fact or principle, some addition of more or less importance to the sum of human knowledge, there may come upon us the eager desire to make our discovery known. We may long to be allowed to add our own little stone to the growing temple of science. We may think of the pride with which we should see our names enrolled among those of the illustrious builders by whom this temple has been slowly reared since the infancy of mankind. So we commit our observations to writing, and send them for publication. Eventually we obtain the deep gratification of appearing in print among well-known authors in science. Far be it from me to condemn this natural desire for publicity. But, as your experience grows, you will probably come to agree with me that if the desire were more frequently and energetically curbed, scientific literature would gain much thereby. There is amongst us far too much hurry in publication. We are so afraid lest our observations or deductions should be forestalled—so anxious not to lose our claim to priority, that we rush before the world, often with a half-finished performance, which must be corrected, supplemented, or cancelled by some later communication. It is this feverish haste which is largely answerable for the mass of jejune, ill-

digested and erroneous matter that cumbers the pages of modern scientific journals. Here it is that you specially need patience. Before you venture to publish anything, take the utmost pains to satisfy yourselves that it is true, that it is new, and that it is worth putting into print. And be assured that this reticence, while it is a kindness to the literature of science, will most certainly bring with it its own reward to yourselves. It will increase your confidence, and make your ultimate contributions more exact in their facts as well as more accurate and convincing in their argument.

The other danger to which I referred as demanding patience is of an opposite kind. As we advance in our career, and the facts of our investigations accumulate around us, there will come times of depression when we seem lost in a labyrinth of detail out of which no path appears to be discoverable. We have, perhaps, groped our way through this maze, following now one clue, now another, that seemed to promise some outlet to the light. But the darkness has only closed around us the deeper, and we feel inclined to abandon the research as one in which success is, for us at least, unattainable. When this blankness of despair shall come upon you, take courage under it, by remembering that a patient study of any department of nature is never labour thrown away. Every accurate observation you have made, every new fact you have established, is a gain to science. You may not for a time see the meaning of these observations, nor the connection of these facts. But their meaning and connection are sure in the end to be made out. You have gone through the labour necessary for the ascertainment of truth, and if you patiently and watchfully bide your time, the discovery of the truth itself may reward your endurance and your toil.

It is by failures as well as by successes that the true ideal of the man of science is reached. The task allotted to him in life is one of the noblest that can be undertaken. It is his to penetrate into the secrets of nature, to push back the circumference of darkness that surrounds us, to disclose ever more and more of the limitless beauty, harmonious order, and imperious law that extend throughout the universe. And while he thus enlarges our knowledge, he shows us also how nature may be made to minister in an ever augmenting multiplicity of ways to the service of humanity. It is to him and his conquests that the material progress of our race is mainly due. If he were content merely to look back over the realms which he has subdued, he might well indulge in jubilant feelings, for his peaceful victories have done more for the enlightenment and progress of mankind than were ever achieved by the triumphs of war. But his eye is turned rather to the future than to the past. In front of him rises the wall of darkness that shrouds from him the still unknown. What he has painfully accomplished seems to him but little in comparison with the infinite possibilities that lie beyond. And so he presses onward, not self-satisfied and exultant, but rather humbled and reverential, yet full of hope and courage for the work of further conquest that lies before him.

Such is the task in which you may be called to share. When you have entered upon it and have learnt something of its trials and responsibilities, as well as of its joys and rewards, you will look back with gratitude to the training you received within the walls of this College. You will feel even more keenly than you do now how much you owe to the patient kindness and educational skill of your teachers and to the healthy stimulus of contact and competition with your class-fellows. Most heartily do I wish you success in your several careers. Following up the paths which have been opened for you here, may it be yours to enlarge still further the circle of light which science has gained, and to wrest from nature new aids for the service of mankind.

THE BRITISH ASSOCIATION.

BRISTOL MEETING.

SECTION K (BOTANY).

OPENING ADDRESS BY PROF. F. O. BOWER, SC.D., F.R.S., PRESIDENT OF THE SECTION.[1]

III.

THE following considerations influence me in forming an opinion as to the real place of apospory and apogamy in the history of the alternating generations :—

I. The Bryophytes show remarkable uniformity of alternation : irregularities are few ; apogamy is not recorded ; apospory appears rarely, as a physiological refuge for the destitute plant. This uniformity goes along with the protected and dependent condition of the sporophyte. All Pteridophytes have their embryos protected while young, and this seems to have been their primitive condition. The true lesson of the Bryophyta, which include the simplest living Archegoniates, seems thus to be that uniformity of alternation goes with a simple structure, and a protected or dependent condition of the sporophyte ; and this we have reason to believe was the condition of the simpler Archegoniate fruits.

II. The distribution of apogamy and apospory among Archegoniates at large is very irregular ; the Leptosporangiate Ferns are the headquarters ; but they are a peculiarly specialised phylum, with free sporophyte, exposed when mature, though protected while young. They are adapted to special conditions and show a greater plasticity of development than any other Pteridophytes. The Ferns are subject to other abnormalities than apospory and apogamy. The root may develop directly into a shoot, or the apex of the leaf into a bud. I think it has been too readily held that the Ferns occupy a special place as a key to the morphological problem. We should bear in mind how really isolated they are ; they are essentially an extreme, even an extravagant type ; they show the largest sporophylls in the whole vegetable kingdom, with the largest numerical output of spores from each. Many are specialised in accordance with extreme conditions of shade and moisture. These considerations should temper our view of them, not only as material for normal comparison, but also as exponents of abnormality.

III. The fact that in cases of induced apogamy in Ferns archegonia are first produced, clearly shows that in these cases the first intention of the plant is towards a normal production of embryos, while apogamy takes its place as a substitutionary growth. It may remain an open question how far direct apogamy will bear a similar interpretation.

IV. The character of the aposporous and apogamous growths is very anomalous ; their position is not definite ; aposporous growths may arise from the sorus and sporangia, or from the most varied points on the margin or surface of the leaf. With regard to apogamy in Ferns, it appears, as the result of a large number of observations, that though there is an average normal of position, still any one part of the sporophyte—stem, leaf, ramentum, root, sporangium, or even tracheid—may arise, independently of others, from the prothallus. Single sporangia, or groups of them, may appear without vegetative organs of the sporophyte ; leaves without other parts ; in one case, I believe, as many as ten roots have been seen without any other members of the sporophyte ! The close similarity of the parts thus irregularly placed to those formed in regular sequence in the normal plant should be a warning of their abnormality. I cannot see in them any suggestion of a primitive state. Dr. Lang tells me that these exceptional developments form only a small proportion of the individuals in any one culture ; still they are there, and those who hold that apogamous developments are a suitable basis for morphological argument must not pick and choose those cases which suit their views, but must take even the most extravagant into careful estimation. My own view is that these anomalous growths are not a safe guide to past history. But looked upon as the result of a recently acquired transition from one generation already established to the other, following nuclear changes, in the one case of reduction after insufficient nutrition, in the other of doubling of the chromosomes following on plethora, apospory and apogamy are at least intelligible. We shall understand how the transition may take place at one point or at many, while the irregularity of the parts produced offers no morphological difficulty ; it is rather what might have been anticipated if the transition were a ready consequence of the conditions we have noted.

Lastly, a word on Dr. Scott's utilitarian argument. He remarks, "a mode of growth which affords a perfectly efficient means of abundant propagation cannot, I think, be dismissed as merely teratological." We must be clear that utility is no certain evidence of antiquity. As refuges for the physiologically destitute, apogamy and apospory may play an important part *now*, and in so far are not to be dismissed as mere freaks of nature. But in my view they would rank, as regards utility pure and simple, with the formation of adventitious buds on the root-system of a Poplar that has been felled ; or with the bulbils which replace the flowers in so many mountain species ; neither

[1] Continued from p. 91.

these, nor, I think, aposporous or apogamous growths, throw any direct light upon the story of descent.

To sum up then, not only do I find that the facts in our possession, including the wildest anomalies, are consistent with an antithetic theory, but a comparison of normal forms seems to me to support the opinion that the sporophyte has appeared as the result of gradual elaboration from the zygote, a fresh phase having been thus gradually intercalated in the course of evolution. This idea first clearly stated by Celakovsky in 1868, was developed by him in subsequent writings. I endeavoured to place it on a footing of adaptation to external conditions, in 1890; and in 1897 we find Strasburger restating the position in terms almost identical with my own, but upon a basis of nuclear detail which had not been dreamed of when the view was first propounded. Dr. Scott has enthusiastically appreciated the double verification of the forecasts of Prof. Pringsheim; I think that the way in which the antithetic theory is found to work in with the nuclear details recently discovered appeals quite as strongly to my mind.

In the course of this discussion I have not been anxious to point out such difficulties as beset the homologous view: all I have attempted here has been to set aside some of the difficulties which have been suggested in opposition to an antithetic view, and to show that the latter theory will adequately cover the facts.

Returning now to our general inquiry on homology, we see that on the antithetic view the two generations are not *homogenetic;* but they may be in a high degree *homoplastic*, and this homoplasy may be impressed upon the two generations, even in the same species, as in some Lycopods. I have never felt the cogency of the fact that the gametophyte of *L. cernuum* is somewhat similar in outline to the young sporophyte. Both generations are exposed to similar circumstances, and may be reasonably expected to have reacted alike. Moreover, the similarity of form of the "leaves" of prothallus and plant is but slight, and is not maintained in allied species. Their arrangement is variable. Between them also lies the essential structural difference, so widespread among Archegoniate plants, that in the sporophyte stomata and intercellular spaces are present, in the gametophyte they are absent. These are just such differences as point to homoplastic development. More commonly, however, the homoplastic development is only seen in distinct organisms, and in this sense we shall rank the leaf of the Moss as the homoplast, but not the homogene, of the leaf of a Lycopod or of a Fern.

THEORY OF THE STROBILUS.

Some years ago I submitted to the Section a theory of the strobilus in Archegoniate plants. Comparisons were drawn between Pteridophytes and Bryophytes, and it was suggested that the origin of the strobilus of the former was "from a body of the nature of a sporogonial head." I specially pointed out at the time that my object was not a mere hunt after homologies, but to obtain some reasonable view of *the methods of advance* in Archegoniate plants. I wish to lay special stress upon this, for some appear to think that by denying an homology which I have not been at pains to maintain, they invalidate this search after the methods of advance. The Bryophytes as we now see them are our best guides in the search after these methods, even though they may not have been in the direct line of descent of Vascular Plants. As regards the comparison of the strobilus with a sporogonial head, I wish to make it clear that a *Moss* sporogonium is not specially indicated. The expression used has been "the origin of the strobilus from a body of the nature of a sporogonial head"—that is simply a part of the sporophyte which bears spores internally as distinct from a lower vegetative region. We see in more than one sequence of Bryophytes how in a sporogonial head, as thus defined, the spore-production becomes restricted in extent, and relegated towards a superficial position by the formation of a central sterile mass. I am ready to join Dr. Scott in his confession of inability to find anything like an intermediate form between the spore-bearing plant of the Pteridophyta and the spore-bearing fruit of the Bryophyta, and to agree that at the best there is nothing more than a remote parallelism not suggestive of affinity; but none the less I think we should continue to search among the Bryophyta for suggestions as to the *methods* of advance, and to have confidence in transferring these ideas across the gulf, for I believe this to be both a reasonable and a promising method of study.

DORSIVENTRALITY.

Interesting questions arise in connection with dorsiventral structure. In the Equisetineae, and almost all Lycopodineae, the strobilus is of the radiate type, therein corresponding to the radial structure of typical sporogonia. While certain Ferns are of the radiate type, others are conspicuously dorsiventral, even from their earliest embryonic state. Dorsiventral structure also appears in the vegetative region, and sometimes, though rarely, in the strobilus of *Selaginella.* Prof. Goebel, in a chapter of his "Organographie," the publication of which may be recognised as the leading event in the morphological studies of the year, discusses the origin of the dorsiventral state in a number of examples, and his results have a most interesting bearing on our theory of the strobilus.

He shows in the case of *Vaccinium Myrtillus* how the first shoot of the seedling is orthotropic and radial; the lateral shoots, formed after the apical growth of this is arrested, are also orthotropic, but the lateral shoots of higher order become plagiotropic with leaves in two lateral rows. He points out the intermediate steps from one condition to the other, and how finally the growing point itself is influenced by the external agency (apparently light), which leads to a change of the leaf-arrangement. This seems to be the case in many other Phanerogamic plants.

A particularly interesting account is also given of similar changes in *Selaginella.* Some eight species are orthotropic, radial, and isophyllous. *S. sanguinolenta* shows a direct response to external conditions, being upright and isophyllous in bright and dry situations, plagiotropic and anisophyllous in damp and shady situations. The bulk of the genus are, however, either plagiotropic and anisophyllous throughout, or some may have an early orthotropic stage. But he concludes that even in "habitually" anisophyllous *Selaginellas* we have to do with an adaptive character, induced probably by light.

We see then good evidence that in certain cases the dorsiventral shoot is a result of adaptation, and the radial probably the primitive. Was this always so? We need not discuss the case of the gametophyte, as the problem there is even more varied and difficult, and does not at the moment engage our attention. But the question whether in the sporophyte the radial was in all cases the primitive type is clearly related to our theory of the strobilus. The sporogonia of Bryophytes are, with few exceptions, orthotropic, and almost uniformly radial; exceptions such as *Diphyscium* and *Buxbaumia* have been shown to have an interesting relation to the incidence of light, and are readily recognised as derivative. The distinctively strobiloid Pteridophytes mostly maintain this radial structure; this may be so both in strobilus and vegetative organs, as in *Equisetum*, *Isoetes*, in most species of *Lycopodium*, and in some *Selaginellas;* or the vegetative region may be dorsiventral, and the strobilus return to the radial type, as in some species of *Lycopodium* and most *Selaginellas;* but in some *Selaginellas* even the strobilus may be dorsiventral.

In the Ferns the case is less obvious; the large size of the leaves, combined often with a dorsiventral structure of the shoot, makes a comparison with a radial strobilus less easy. Goebel has pointed out that in many dorsiventral Ferns the dorsiventrality is already defined in the *punctum vegetationis*, and does not depend upon a subsequent shifting of the parts. But it should be remembered how many Ferns are orthotropic and radial; that almost all the large genera include species with simple unbranched leaves. Further, the series of the Ophioglossaceae, possibly a distinct phylum from the true Ferns, may be held to illustrate a progressive elaboration of the leaf, from smaller leaved forms which are orthotropic and radial, to larger-leaved forms, which are sometimes orthotropic and radial (*Botrychium*), sometimes plagiotropic, and dorsiventral (*Helminthostachys*). It is not, I think, improbable that these, and also the true Ferns, are referable in origin to an orthotropic strobiloid type, with radial structure. This opinion was in substance suggested in 1894 at Oxford; these recent observations of Goebel on the derivative nature of dorsiventral shoots strengthen the position then taken up, while they supply us with fresh examples of homoplastic development.

CONCLUSION.

This discussion was entered on with a view to finding whither phylogeny as a basis of morphology would lead us. However unprepared we may be to pursue it with certainty into detail, or

to apply a terminology to the sequences which we recognise, we must, I think, accept phylogeny as the natural basis for morphology. I do not think that any middle course between this and an artificial system is possible or reasonable. But here we launch ourselves upon a sea of uncertainties on which we must keep our course with care. Following it, we think we espy certain great movements in nature. We may recognise what we believe to be a true evolutionary sequence, but who is to say whether it is a progressive or a retrograde sequence? It may be even one divergent from some middle point. Our best friend may read the sequence in opposite order to ourselves and arrive at a diametrically opposite conclusion. There is no finality to this judging of probabilities, a fact which should be always before the mind, especially in the warmer moments of discussion.

It is interesting to trace the parallel between the progress of classification of plants as a whole, and that of the classification of their parts. In each case the earlier systems were artificial. We may compare the Linnaean system of taxonomy with the Hofmeisterian organography: in both the rigid application of a preconceived method placed incongruous things in juxtaposition, in each case a widening of the basis of the classification has resulted in a redistribution on more natural lines. The present ideal of taxonomy is the same as that of the phylogenetic organography, viz. to group according to descent. The limitations are alike: systematists and morphologists both find their greatest difficulty in the incompleteness of the record, and the frequent isolation of the thing to be classified.

But without following the obvious parallel further, we may now briefly review our position as regards organography, and the following categories are to be recognised, though they graduate almost imperceptibly into one another:—

Homogeny.—(*a*) *Repetition* of the individual part in successive generations, with the same number and position. This is exemplified by the cotyledons, the foot, and first root.

(*b*) *Essential correspondence* of parts varying in number and position, but corresponding in character and development, produced in a regular sequence; *e.g.* most cases of continued embryology.

(*c*) *Transferred position* of parts, similar in origin and structure to those produced in regular sequence; *e.g.* roots, adventitious buds, sori of *Aspidium anomalum*, aposporous and apogamous growths, many monstrosities; these we may believe to result from a transfer of inherited developmental capability.

Homoplasy.—This may be recognised with varying degrees of probability; starting from cases where the question of community of descent is open (as with nearer circles of affinity), and proceeding to those in which distinct evolution is virtually certain. It remains for future investigation to clear up doubtful points. Meanwhile, taking the case of leaves for the purpose of illustration, we may contemplate the following possibilities:—

(*a*) A possible origin of two homoplastic series of leaves in the same plant, and the same generation (*Phylloglossum*).

(*b*) Two homoplastic series in the same plant, but in different generations (*Lycopodium cernuum*).

(*c*) A possible distinct origin of homoplastic leaves in distinct phyla, but in the same generation (sporophyte of Ferns, Lycopods, Equiseta).

(*d*) A distinct origin of homoplastic leaves in distinct phyla, and distinct generations (*e.g.* leaves of Bryophyta and of Pteridophyta).

Now *Homology* has been used in an extended sense as including many, or even all, of these categories. It seems plain to me that this collective use of the term homology carries no distinct evolutionary idea with it; it indicates little more than a vague similarity; the word will have to be either more strictly defined or dropped. The old categories of parts based upon the place and mode of their origin are apt to be split up if the system be checked by views as to descent. Comparison, aided by experiment, supersedes all other methods, and the results which follow raise the question of terminology of parts which have arisen by parallel development.

In parts which are of secondary importance, such as stipules, pinnae, the indusium, hairs, glands, the inconstancy of their occurrence points to independent origin by parallel development in a high degree; in parts of greater importance, such as leaves, a parallel development may also be recognised, though in a less high degree; in the case of sporangia their acceptance as a category *sui generis* dispelled the old view of their various origin from vegetative parts; but we must remember that this does not by any means exclude a parallel development also in them, by enlargement and septation from some simpler spore-producing body, though this is not yet a matter of demonstration. Finally, the sexual organs are probably homogenetic in all Archegoniate plants, but we have no proof that sexuality arose once for all in the lower plants; the probability is rather the contrary. Thus we may contemplate as very general a polyphyletic origin of similar parts by evolution along distinct lines, but resulting, it may be, in forms essentially similar.

There are two extreme courses open to those who wish to convey clearly to others such matters as these; the one is to use a separate term for each category of parts, which can be followed as maintaining its individual or essential identity throughout a recognised line of descent—in fact, to make a polynomic terminology of members run parallel with a polyphyletic development. The other course is to make it clear always in the use of terms applied to parts, that they do not convey any evolutionary meaning, and to use them only in a descriptive sense. Perhaps the former is the ideal method, and it may be a desirable thing, as polyphyletic origins of parts become more established, that the terminology should be brought to reflect at least the more important conclusions arrived at. How this may be done we leave for the future to decide, though I have indicated a first step in the case of the leaves of Mosses and Ferns.

But, for the present, the whole matter is still so tentative that it is well to be content with something which falls short of the ideal, and to maintain the usual terms, such as stem, leaf, root, hair, sporangium, &c., as simply descriptive of parts which correspond as regards general features of origin, position, and nature; but with no reference either, on the one hand, to conformity to any ideal plan, or, on the other, to any community by descent—in fact we shall preserve the original pre-Darwinian sense of these words, which was purely descriptive, and avoid any attempt to read into them any accessory meaning.

A special interest attends those cases of transfer of inherited developmental capability where a part appears with its normal characters, but in a position which is not usual, such as the transfer of the sori of *Aspidium anomalum*; comparable with these transfers on the one hand are those apogamous growths where roots, leaves, ramenta, sporangia may arise independently out of the usual succession. These may be compared, on the other hand, with those interpolations of extra parts, such as the accessory stipules in the stellate Rubiaceae, the extra stamens in Rosaceae, &c. We are unable as yet to say what it is which determines the position and mode of origin of parts; I do not myself think that Sachs's hypothesis of "Stoff and Form," involving ideas of material differences which have not been demonstrated, will advance the question so much as a careful following of the details in the origin of the parts, say in some of these apogamous growths. Here we see the plant body in a sense analysed before us; any one part may be produced separately from any other. An elucidation of how any one of these is initiated and determined should lead to a knowledge of the influences which act also in the normal sequence, and determine the origin of parts in the plant body at large.

I have attempted to touch upon some of those questions in the Morphology of Plants which specially interest us at present, and I dare say in doing so have revealed to you some of the special weaknesses of this branch of the science. The want of finality in this unravelling of history without documents, the ample latitude for difference of opinion, according to the relative weight attached by one or another to the same facts: these are difficulties inherent in the very nature of our study, while to many minds they increase rather than diminish its attractions. Nevertheless the progress of morphology in late decades has plainly been towards a truer appreciation of how divers forms have originated, and so towards a better recognition of affinities. Seeing that this is clearly the main trend, we may take heart as to the advancement of morphological knowledge. We shall not allow ourselves to be deterred by reason of the want of finality or the deficiency of evidence, however strongly we may feel the weight of these difficulties. We shall rather try to make the best of such evidence as we possess, with the full confidence that, however insoluble the problem of descent may really be, inquiry along scientific lines will at least lead us nearer to the goal.

AN AMPERE BALANCE.[1]

THE Report of the Committee on Electrical Standards for 1897 ended with the following paragraph:—"It thus appears to be a matter of urgent importance that a redetermination of the electro-chemical equivalent of silver should be made, and that the general question of the absolute measurement of electric currents should be investigated. . . ." This work we were asked by the Committee to carry out, and a grant of 75*l.* was voted in its aid. We were thus led to examine into the methods which had been employed by Lord Rayleigh, Prof. Mascart and others, for determining the absolute value of a current, as well as to consider some other methods which have not, as far as we know, been hitherto used.

After much consideration we decided to adopt a form of apparatus which, while generally resembling the type employed by some previous experimenters, possessed certain important differences; and, before expending any part of the grant of 75*l.*, to construct, without expense to the British Association, the following preliminary ampere balance.

On a vertical cylinder about 17 inches high and 6·8 inches in diameter we wound two coils, about 5 inches in height, separated by an axial distance of 5 inches. The coils consisted each of a *single* layer of about 170 convolutions of wire, and were wound in opposite directions. From the beam of a balance there was suspended, inside this cylinder, a light bobbin about 4 inches in diameter, on which was wound a coil about 10 inches long consisting of a *single* layer of 360 convolutions, and the whole apparatus was so adjusted that when the beam of the balance was horizontal the inner and outer coils were coaxial, and the top and bottom of the inner suspended coil were respectively in the mean planes of the outer stationary coils.

This arrangement was adopted because with coils consisting of only one layer the geometrical dimensions could be accurately determined, and because the shapes of the coils lent themselves to the use of the convenient formula, readily expressible in elliptic integrals, for the force, F, between a uniform cylindrical current sheet and a coaxial helix, viz.:—

$$F = \gamma\gamma_h(M_1 - M_2)$$

where γ is the current per unit length of the current sheet, γ_h the current in the helix, and M_1 and M_2 the coefficients of mutual induction of the helix and the circular ends of the current sheet.[2]

The value of a particular current of about 0·63 ampere having been determined *absolutely* by means of this apparatus, the rate at which it would deposit silver under specified conditions was ascertained indirectly, by observing its silver value on a Kelvin balance which had been kept screwed down in a fixed position for several years past, and which had been calibrated many times during that period by reference to the silver voltameter.

The result of this preliminary investigation showed that the silver value of the *true* ampere was so nearly equal to the reputed value, viz. 1·118 milligramme per second, as to require the use of an apparatus still more perfectly constructed, and therefore of a much more expensive character, to enable the error, if any, in this value to be ascertained with accuracy.

We, therefore, started on the design of the instrument, of which we now submit the working drawings, and for the future construction of which we would ask for a grant of 300*l.*, including the unexpended grant of 75*l.* voted last year.[3] And we anticipate that this new piece of apparatus may prove worthy of constituting a national ampere balance, the counterpoise weight for which will be determined purely by calculation based on the dimensions of the instrument, the number of convolutions of wire in the three coils, and the value of the acceleration of gravity at the place where the instrument may be permanently set up. In this particular it will differ entirely from the "Board of Trade Ampere Standard Verified, 1894," which has had its counterpoise weight adjusted so that the beam is horizontal when a current passes through the instrument, which will deposit *exactly* 1·118 milligramme of silver per second under specified conditions. In fact, the proposed ampere balance and the existing ampere standard will differ exactly in the same way as do a Lorenz apparatus and the "Board of Trade Ohm Standard Verified, 1894."

We have to express our thanks to Mr. Mather for taking charge of the construction and use of the preliminary apparatus, for checking all the calculations in connection with the determination of the electro-chemical equivalent of silver that was made with it, as well as for superintending the making of the working drawings of the new ampere balance. We have also to thank Messrs. W. H. Derriman and W. N. Wilson, two of the students of the City and Guilds Central Technical College, for their cordial assistance in carrying out the work.

[2] *Proceedings* of the Royal Society, vol. lxiii., "On the Calculation of the Coefficient of Mutual Induction of a Circle and a Coaxial Helix, and of the Electro-magnetic Force between a Helical Current and a Uniform Coaxial Circular Cylindrical Current Sheet." By Prof. J. V. Jones.

[3] This grant of 300*l.* has since been made.

GEOLOGY OF BIRMINGHAM.

ONE of the most important geological memoirs issued of late years is the "Sketch of the Geology of the Birmingham District," by Prof. Lapworth, F.R.S., with contributions by Prof. W. W. Watts and Mr. W. Jerome Harrison: a companion work to that on the "Geology of South Shropshire," by Profs. Lapworth and Watts, issued four years ago. The present work, like the one just mentioned, was prepared with special reference to the areas to be visited by the Geologists' Association during their long summer excursion. It is not merely a lucid summary of the facts already made known; it contains the latest results of the work done by the author and his associates. The "Birmingham district" is admittedly a large one, being the region within a radius of about thirty-five miles from the city. Thus we find references to the Archæan or Pre-Cambrian rocks of Malvern and the Abberley Hills, of the Wrekin and Lickey Hills, of the Caldecote district and Charnwood Forest. It is stated that the Charnwood or "Charnian Rocks" are theoretically paralleled with the Lower Longmyndian and its volcanic equivalents, and the Caldecote rocks, together with the Barnt Green rocks of the Lickey, are grouped with the Upper Longmyndian and Uriconian.

In the Cambrian areas order is established by comparisons of the quartzites of the Wrekin, Hartshill, and the Lickey. The Hartzhill quartzite is shown to be composed of three main divisions, the upper one containing a band of *Hyolithus*-limestone, the fauna of which answers in part to the *Olenellus*-zone of other regions. Hence this upper or "Camp Hill quartzite" of Hartshill is compared with the Comley or Hollybush Sandstone of the Shropshire and Malvern successions. The Stockingford shales, which overlie the Hartshill beds, are divided into three groups which represent the *Paradoxides* or Menevian zone and portions of the Lingula flags. Comparisons are then made between the Warwickshire strata and those in the north-west of Scotland, the place of the argillaceous Stockingford shales being there taken by the Durness Limestone group.

The Silurian strata (Llandovery to Ludlow), and the Carboniferous system are fairly well known, and the leading facts are pointed out. With reference to the Permian rocks it is observed that, as a general rule, they follow conformably upon the Upper Coal Measures of the district. The origin of the Permian breccias is discussed, and the opinion of Mr. W. Wickham King is quoted to the effect that they are largely torrential deposits formed more or less of scree and talus, swept down in flood times from the sides of steep hill-slopes near at hand. The similar views of Mr. Horace T. Brown respecting these strata in the country near Burton-on-Trent might have been mentioned.

A useful account is given of the Triassic strata which occupy so large a portion of the Birmingham district, and this is followed by a brief notice of the Rhætic beds and Lias. The petrology of the Birmingham district is dealt with by Prof. Watts, and the glacial drifts are described by Mr. Harrison. In conclusion there is a summary of the history of geological research among the rocks of the district.

The entire work is full of valuable information and suggestions, the stratigraphical facts being clearly stated and supported by palæontological evidence where that is forthcoming. Hence for a long time to come, this memoir, which is well illustrated with sections and pictorial views, will be the standard work of reference on the area of which it treats; and the Geologists' Association may be heartily congratulated on having received so important an addition to its *Proceedings*. Of this publication it constitutes the whole of part 9 of volume xv., and it is issued to the public at the price of 1*s.* 6*d.*

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The Junior Scientific Club held their 195th meeting in the Physiological Lecture Room of the Museum on Friday, November 25. Mr. M. Burr (New College) read a paper on "Collecting in South-Eastern Europe," which was illustrated by lantern slides from photographs taken during his recent journey through Herzegovina and Montenegro. Mr. J. M. Wadmore (Trinity) followed with a paper on "Sun-spots and Faculae." The number of new members this term has been forty-seven.

Cambridge.—The following summary of the results of the Cambridge Scholarship Competition is sadly instructive :—

Scholarships and Exhibitions at Cambridge.

The allied Colleges.—Pembroke, Gonville and Caius, Kings, Jesus, Christ's, St. John's, Emmanuel.

			£
Classics	35	scholarships and exhibitions, value	1710
Mathematics ...	19	,, ,, ,, ,,	1110
Modern languages	3	,, ,, ,, ,,	120

It will be seen that Trinity and Clare have again treated science quite fairly, as they did last year ; but 3040*l.* in literature and mathematics, and only 390*l.* for science, is a very unsatisfactory distribution of prizes, and does not encourage scientific education in our schools and colleges.

Mr. W. H. Preece, C.B., F.R.S., will distribute the prizes to students at the Merchant Venturers' Technical College, Bristol, on December 21.

The new building extension of the Borough Polytechnic Institute, including workshops and gymnasium, will be formally opened on Thursday next, December 8.

Mr F. P. Barnard having found himself unable to accept the headmastership of University College School, London, the Council have offered it to Mr. J. Lewis Paton, assistant master at Rugby School, who has accepted it.

Mr. E. H. Todd, a student at the South-Western Polytechnic Day College for men, has been appointed to an open exhibition in Physics and Chemistry at Christ Church, Oxford, of the value of 80*l.* per annum, tenable for four years.

According to the twenty-fifth quarterly statement of the President of the University of Chicago, there were 1421 students in attendance during the summer quarter, of whom 591 were in the graduate schools. The assets of the University are valued at about 9,000,000 dollars. The income was 706,973 dollars, and the expenditure 678,399 dollars.

The Commission appointed under the University of London Act, 1898, consisting of Lord Davey (chairman), the Bishop of London, Sir William Roberts, Sir Owen Roberts, Prof. Jebb, Prof. Michael Foster, and Mr. E. H. Busk, with Mr. Bailey Saunders as secretary, has commenced its sittings. The office of the Commission is No. 32 Abingdon Street, Westminster, S.W.

A scheme for the establishment of a Gordon Memorial College at Khartum has been put forward by Lord Kitchener. It is proposed that the principal teachers should be British, and that the supervision should be vested in the Governor-General of the Sudan. The teaching, in its early stages, would be devoted to purely elementary subjects, such as reading, writing, geography, and the English language. Later, and after these preliminary stages had been passed, a more advanced course would be instituted, including a training in technical subjects, specially adapted to the requirements of those who inhabit the valley of the Upper Nile. The fund required for the establishment of the college Lord Kitchener estimates at 100,000*l.*, of which 10,000*l.* would be required for the initial outlay, and the remainder invested for the maintenance of the institution. He announces that the Queen has consented to become patron and the Prince of Wales vice-patron, of the movement, and that a general Council of the leading men of this country is in course of formation.

SOCIETIES AND ACADEMIES.

London.

Physical Society, November 25.—Mr. Shelford Bidwell, F.R.S., President, in the chair.—Mr. R. A. Lehfeldt read a paper on the properties of liquid mixtures, being Part iii. of his communications on that subject. It deals with partially miscible liquids. Measurements are given of the vapour-pressure of mixtures of phenol and water. This pair of liquids is completely miscible above 68° C., and incompletely miscible below that temperature. The law of equilibrium between incomplete mixtures and the vapour over them is investigated, especially at "the critical point," *i.e.* at the point where incomplete miscibility passes over into complete miscibility. It is pointed out that normal organic liquids always mix completely. Ethylene dibromide and formic acid mix on boiling, and separate into two layers when cold. The curves representing the cases of complete mixture are comparable in shape with those previously obtained by Mr. Lehfeldt for mixtures of alcohol and toluene, but they show a still flatter maximum ; so much so that 60 per cent. to 70 per cent. of phenol may be added to water without appreciable effect on the vapour-pressure. To verify this point, a differential pressure-gauge was designed ; the construction and method of using are given in the paper. The behaviour of the liquid is apparently the same above and below the critical point. At temperatures not too close to the critical point the vapour-pressure of a saturated mixture is approximately the sum of the partial pressures, calculated for the two saturated solutions according to Raoult's law. Diagrams are drawn showing the characteristic surface for phenol-water mixtures, with the freezing-points of water and of phenol traced out. Phenol melts under water at 1°·5 C., and forms a cryohydrate containing 4·83 per cent. phenol, melting at − 1·0 C. Prof. S. Young (abstract of communication) : The statement of Mr. Lehfeldt that normal organic liquids always mix completely, should be qualified. There are pairs of normal organic liquids which, though miscible in all proportions, approximate closely to partially miscible liquids, *e.g.* benzene (b.p. 80 C.) and normal hexane (b.p. 69° C.). When American petroleum is fractionally distilled, the benzene which is present in small quantity does not come over at about 80°, but mostly at about 65° ; the most probable explanation appears to be that benzene and hexane behave, as regards distillation, like miscible liquids, a view which is confirmed by an investigation of the boiling-points and also of the specific gravities of mixtures of the two hydrocarbons, an account of which has lately been read before the Chemical Society by Messrs. Young and Jackson. The boiling-point curve is similar in general form to that of phenol and water, as shown by Mr. Lehfeldt, though the deviation from the ordinary form is not so marked. Ten per cent. of benzene has practically no influence on the boiling-point of normal hexane, but 10 per cent. of hexane lowers the boiling-point of benzene nearly 3 C. Also there is always expansion on mixing benzene and hexane, the maximum reaching about 0·4 per cent. Dr. S. P. Thompson asked whether any relation

had been observed between the vapour-pressure and the surface tension of the mixtures. Mr. Lehfeldt was not sure whether the surface-tensions of the components pass into one another at the critical point of mixture.—Mr. L. N. G. Filon then gave an account of his paper on certain diffraction fringes as applied to micrometric observations; it is to a great extent a critical investigation of a paper by A. A. Michelson on the same subject (*Phil. Mag.*, vol. xxx. pp. 1–21, July 1890). Michelson there describes a method for measuring the angular distance between the components of a double star, or the angular dimensions of very small celestial bodies, by means of interference-fringes, using two adjustable slits in front of the objective of a telescope. If the star is double, or if it has an appreciable disc, then by widening the distance between the slits, the fringes become fainter, and in some cases almost vanish. But, by still further widening the slit, the fringes reappear, disappear, and so on. In the paper (*l.c.*) Michelson develops the law of these appearances and disappearances, and gives an expression for the ratio of the angular distance between the components of the double star, or the angular radius of the single source, to the distance between the slits, *on the assumption that the slits are infinitely long and infinitely thin.* Mr. Filon considers that this assumption is unjustified by the conditions of measurement; he reviews the original investigation, and modifies the results. He then proceeds to find equations to represent the intensity of light in the focal plane, for a point source, and for a two-point source. These fringes are only visible over a certain rectangle, called "the rectangle of illumination" of the source. In the case of a two-point source, if the distance perpendicular to the slits, between the geometrical images of the two points, is an integer-multiple of the distance between two fringes, the maxima of one system correspond with the maxima of the other, the fringes overlap and their intensity is augmented. If, however, this distance should be an odd multiple of the half-distance between the fringes, the maxima of one system correspond to the minima of the other, and if *the fringes that are superposed* are of similar intensity, the fringing is nearly obliterated, a result that agrees with Michelson's law. But it is now shown that for this phenomenon to occur (1) the rectangles of illumination of the two sources must overlap to a very large extent, this consideration was neglected by Michelson, and (2) the angular distance between the two stars measured parallel and perpendicularly to the slits, must be less than a definite amount, depending upon the wave-length, and the length and breadth of the slits. In astronomical cases, the second condition is generally satisfied. If the rectangles of illumination do not overlap they can be respectively distinguished, and thus the star can be resolved by direct observation. If, however, an accurate measurement of the distance between the components is required, by Michelson's method, the rectangles must be made to overlap. The paper includes an investigation of a refractometer that Michelson (*l.c.*) proposed to use for increasing the effective aperture of a telescope; it is shown that Michelson's law is generally true for that instrument, but certain limitations are pointed out. Extended sources are next considered, and also the shape and size of the object. The paper concludes with the description of a method, by means of which the ellipticity of a very small disc may be measured by these diffraction fringes in the special case where Michelson's law holds good. In reply to a question from Prof. S. P. Thompson, Mr. Filon said that the minimum breadth of slit with which he had found it practicable to work, using monochromatic light with his telescope, was about half a millimetre.—The President proposed votes of thanks, and the meeting adjourned until December 9.

Chemical Society, November 17.—Prof. Dewar, President, in the chair.—The following papers were read:—Determination of the constitution of fatty acids, Part i., by A. W. Crossley and H. R. Le Sueur. The authors have devised a general method for determining the constitution of a fatty acid of the type $CH_2X.CH_2.COOH$; the method has been proved upon valeric, isovaleric and isobutylacetic acid.—The crystalline form of iodoform, by W. J. Pope. Iodoform is deposited from acetone solution in magnificent hexagonal crystals, of which measurements are given.—The characterisation of racemic compounds, by F. S. Kipping and W. J. Pope. Ladenburg states that if a mixture of an externally compensated substance with one of its active components, deposits on fractional crystallisation fractions of different specific rotations, the compensated substance is racemic; if it is not racemic, the various fractions have the same specific rotation. The authors show that this rule does not hold.—The occurrence of orthohydroxyacetophenone in *Chione glabra*, by W. R. Dunstan and T. A. Henry. The wood of *Chione glabra* has a strong somewhat foecal odour owing to its containing orthohydroxyacetophenone.—Preparation of hyponitrite from nitrite through oxyamidosulphonate, by E. Divers and T. Haga. Sodium carbonate and sulphur dioxide convert sodium nitrite into oximidosulphonate, which on hydrolysis yields sodium oxyamidosulphonate; the latter is decomposed into hyponitrite and sulphite by potash. These facts lead to a good method of preparing hyponitrites.—Absorption of nitric oxide in gas analysis, by E. Divers. A concentrated alkaline solution of sodium or potassium sulphite rapidly absorbs nitric oxide, and may be used for this purpose in gas analysis.—Interaction of nitric oxide with silver nitrate, by E. Divers. Silver nitrate decomposes in a current of nitric oxide at lower temperatures than in air or carbon dioxide; the products are the same in the two cases, namely, silver, silver nitrite and nitrogen peroxide.—Preparation of pure alkali nitrites, by E. Divers. Nitrous gases containing excess of nitric oxide convert potassium or sodium hydroxide or carbonate into nitrite in absence of air; no nitrate is formed.—The reduction of an alkali nitrite by an alkali metal, by E. Divers.—Hyponitrites: their preparation by sodium or potassium, by E. Divers.—Paranitro-orthanisidine, by R. Meldola. A number of derivatives of *p*-nitro-*o*-anisidine are described.

Mathematical Society, November 10.—Prof. Elliott, F.R.S., President, in the chair.—The President feelingly alluded to the losses to the Society occasioned by the recent deaths of Mr. Walter Wren and Dr. J. Hopkinson, F.R.S.—The Treasurer read his report, which was a favourable one. Its reception was moved by Mr. A. B. Kempe, F.R.S., seconded by Mr. S. Roberts, F.R.S., and carried unanimously. The ballot was then taken, with the result that Lord Kelvin, G.C.V.O., was elected President, and Messrs. Elliott, F.R.S., H. Lamb, F.R.S., and Lieut.-Colonel Cunningham, R.E., Vice-Presidents. The other members of Council of the last session remain in office, with the exceptions noted on p. 602 (NATURE, vol. lviii.). The retiring President having vacated the chair, his place was taken by Lieut.-Colonel Cunningham, who called upon Prof. Elliott to read his address, entitled "Some Secondary Needs and Opportunities of English Mathematicians," of which the following is a brief abstract. The address congratulated the Society on the work it had done during the last two years, and in particular on the printing in its *Proceedings* of Sylvester's "Outlines of Seven Lectures on the Partitions of Numbers." It referred to some of the losses by death which had occurred during the two years among mathematicians and members of the Society. It expressed gratification at the holding at Zürich in 1897 of an international Congress of mathematicians, and at other signs of growing co-operation among mathematicians of different nationalities. This co-operation, which the history of the Society had proved to be so valuable at home, should in every way be encouraged on the widest possible scale. Reference was made to some advantages which had accrued from co-operation and mutual encouragement in the history of the Society, and it was in particular enforced that much stimulation had once been exercised by the actual meetings of the Society, in ways for which opportunity still presented itself. The influence which the Society had exercised in widening the scope of British enterprise in pure mathematics was dwelt upon at some length, and illustrated by reference to a former need for advanced and comprehensive treatises on modern subjects, which had been inspiringly exposed by one of the Society's earlier Presidents, Prof. Henry Smith, and since his time largely satisfied. Secondary work was necessary that the transition from narrow to widened views of mathematical opportunity be effected surely and without discouragement. The passion among us for examination into elegant incidentals, which shows itself in the fascination exercised by problem making and solving, must be reckoned with and, in the speaker's opinion, not discouraged. The effort must be to increase the range of interest among students without weakening the facility of acquiring that interest. Unambitious work of definitely educational intention, in subjects now made known to the select few by ambitious treatises, is needed. Instructors are required where leaders have been found. The logical improvement of elementary teaching is proceeding. Unassuming, partial and introductory books of didactic character on modern subjects are wanted. Opportunities for didactic work, and for the utilisation of our love of

detail, were illustrated by reference to subjects connected with the Theory of Functions, and with Lie's Theory of Continuous Groups. Greater attention to historical and bibliographical work, in order to disseminate interest in mathematical advancement, was also advocated. It was noticed with satisfaction that a great stimulus to the production of specialist literature of this kind in our own tongue had been given by the American Mathematical Society. In conclusion, thankful acknowledgment was made of the great debt owed by the Society to Mr. Jenkins and Mr. Tucker, who from the days of its infancy had been its honorary secretaries, and of whom the former found it necessary three years ago to claim rest from his arduous duties, and now has had further to ask to be relieved from service on the Council.—On the motion of the chairman, ratified by the members present, Prof. Elliott consented to the publication of the address in the *Proceedings*.—The following papers were formally communicated :—The structure of certain linear groups with quadratic invariants, Dr. L. E. Dickson ; multiform solutions of certain differential equations of physical mathematics and their applications, Mr. H. S. Carslaw ; on the null spaces of a one system and its associated complexes, Mr. W. H. Young ; and on the functions Y and Z which satisfy the identity $4(x^p - 1)/(x - 1) = Y^2 \pm pZ^2$, Prof. L. J. Rogers.

Zoological Society, November 15.—W. T. Blanford, F.R.S., Vice-President, in the chair.—Prof. G. B. Howes, F.R.S., exhibited a series of embryos and five living eggs of the Tuatera Lizard (*Sphenodon punctatus*), which had been sent to him by Dr. A. Dendy, of Christchurch, New Zealand.—Messrs. E. W. L. Holt and L. W. Byrne exhibited specimens and drawings of a small Sucker-fish of the genus *Lepadogaster*, taken at Plymouth, and considered to represent an undescribed species, for which they propose the name *L. stictopteryx*.—Sir G. F. Hampson read a paper giving an account of the classification of the Moths of the subfamily *Pyraustinae* of the family *Pyralidae*, which contained 161 genera. Mr. W. E. de Winton gave an account of the Mammals obtained by Mr. R. McD. Hawker during a recent visit to Somaliland.—Mr. Oldfield Thomas read a paper on the Mammals collected by Mr. J. D. D. La Touche near Kuatun, N.W. Fokien, China, which contained notes on twenty-seven species, two of which, viz., *Vespertilio discolor superans* and *Mus harti*, were described as new.—Mr. G. A. Boulenger, F.R.S., read a memoir entitled "A Revision of the Genera and Species of Fishes of the Family *Mormyridae*," and illustrated it by the exhibition of a fine series of specimens of the family which had been entrusted to him for examination by the authorities of the Congo Free State. According to the author's views the family of *Mormyridae*, as at present known, consisted of eleven genera and seventy-three species, all of which were defined in the paper.—A communication was read from Dr. A. G. Butler, containing a list of the butterflies obtained in the Harar Highlands by Captain H. G. C. Swayne, R.E., one of which (*Mylothris swaynei*) was described as new.—A second communication from Dr. Butler contained an account of a small collection of butterflies made in the Chikala District, British Central Africa, by Mr George Hoare.—A third paper by Dr. Butler contained a list of twenty-one species of butterflies obtained by Mr. R. Crawshay in British East Africa at the end of 1897 and the beginning of 1898.—A communication from Prof. Sydney J. Hickson, F.R.S., contained some notes on the collection of specimens of the genus *Millepora* made by Mr. Stanley J. Gardiner at Funafuti and Rotuma.—Prof. F. Jeffrey Bell communicated a report by Mr. F. P. Bedford on the Holothurians collected by Mr. Gardiner at Funafuti and Rotuma. Eighteen species were enumerated and remarked upon, of which one (*Chiridota intermedia*) was described as new.—Prof. Bell also read a report on the Actinogonidiate Echinoderms brought home by Mr. Gardiner from the same localities. The collection comprised examples of twenty-one species, which were enumerated.—A communication was read from Herr Oscar Neumann containing the description of a new species of Antelope of the genus *Hippotragus* from East Africa, which he proposed to name *H. rufopallidus*.

Royal Meteorological Society, November 16.—Mr. F. C. Bayard, President, in the chair.—A report on experiments upon the exposure of anemometers at different elevations, was presented by the Wind Force Committee. The experiments have been carried out by Mr. W. H. Dines, and Captain Wilson-Barker, on board H.M.S. *Worcester*, off Greenhithe. Five pressure-tube anemometers were employed, the first being at the mizzen royal masthead ; the second and third at the ends of the mizzen topsail yardarm, and the fourth and fifth on iron standards 15 feet above the bulwarks. The results show that the ship itself affected the indications of the lower anemometers, while some low hills and trees, which are a quarter of a mile away from the ship, to the south, and south-west also affected the wind velocity from those quarters. The Committee are of opinion that the general facts deducible from these observations bearing on the situation of instruments for testing wind force are : (1) That they must have a fairly clear exposure to be of much value ; and would appear that for a mile at least all round there should be no hills, or anything higher than the position of the instruments. (2) That on a ship the results may be considered fairly accurately determined by having the instrument 50 feet above the hull, but that on land it will generally be necessary to carry the instruments somewhat higher, to be determined entirely by the local conditions. (3) That no other form of anemometer offers such advantages as the pressure-tube, from the fact that it can be run up and secured easily at this height above a building, and that the pipes and stays can be slight so as to offer no resistance to the wind or cause any deflecting currents. Captain D. Wilson-Barker read a paper giving the results of some observations which he had made on board ship with several hand anemometers with the view of comparing the estimated wind force with that indicated by instruments. Mr. W. Marriott exhibited some lantern slides showing the damage caused by the tornado which burst over Camberwell about 9.30 p.m. on October 29. The damage was confined to an area of about half a mile in extent, and within that space chimney stacks were blown down, houses unroofed, trees uprooted, and windows broken.

Geological Society, November 9.—W. Whitaker, F.R.S., President, in the chair.—On the Palaeozoic radiolarian rocks of New South Wales, by Prof. T. W. Edgeworth David, and E. F. Pittman. Not only in the cherts and siliceous limestones, but also in the jointed claystones which form the prevalent sedimentary rocks of the Tamworth district, radiolaria are found to be distributed in vast numbers. The three chief areas of radiolarian rocks in New South Wales are Bingara, Barraba, and Tamworth, situated in the New England district, between 180 and 270 miles north of Sydney. The fourth area of radiolarian rocks is at the well-known Jenolan caves, about 67 miles due west of Sydney and about 200 miles south-by-west of Tamworth. It is at Tamworth that the radiolarian rocks are developed on a grand scale ; their measured thickness amounts to 9267 feet, after allowing for an immense fault, and neither upward nor downward limit is shown. The rocks consist of jointed claystones, black cherts, lenticular siliceous radiolarian limestones, and coral-limestones. Numerous beds of submarine tuff also occur. The claystones are largely formed of radiolaria. In certain beds of the claystones, and in some of the tuffs as well, impressions of *Lepidodendron australe* are not uncommon ; and beds of radiolarian limestone occur in close proximity to the beds with these plant-remains, and radiolaria moreover abound even in the same rock with the *Lepidodendron*-impressions. In their conclusions the authors point to the remarkably fine grained character of the materials forming the base of the radiolarian cherts, jaspers, and shales, the constituent particles not being more than 0·05–0·025 mm. ($\frac{1}{500}$ to $\frac{1}{1000}$ inch) in diameter. They are of opinion that the radiolaria were deposited in clear sea-water, which, though sufficiently far from land to be beyond the reach of any but the finest sediment, was nevertheless probably not of very considerable depth.—On the radiolaria in the Devonian rocks of New South Wales, by G. J. Hinde, F.R.S. Hand-specimens of the various radiolarian rocks discovered by Messrs. David and Pittman in New South Wales were forwarded to the author, and from them numerous microscopic sections were prepared. Fifty four species belonging to 29 genera have been determined and figured ; all the species and four genera are regarded as new ; excepting a few primitive types of Nassellaria, the forms belong to the Spumellaria. The large majority may be included in the Sphaeroidea and Prunoidea with medullary tests and radial spines. They do not show any near relationship to the radiolaria described from Devonian rocks in Europe, but in some features they resemble the radiolarian faunas of Ordovician age in the south of Scotland, Cornwall, and Cabrières, Languedoc. No other fossils beyond a few simple sponge-spicules and, on two or three horizons, some fragmentary impressions of *Lepidodendron*

australe, have been found in association with the radiolaria. These New South Wales radiolarian deposits are by far the most extensive of any hitherto known, and they are remarkable not only for their great thickness, but also for the manner in which the radiolaria are preserved in the limestones, tuffs, and claystones.

CAMBRIDGE.

Philosophical Society, November 14.—Mr. J. Larmor, President, in the chair.—Orthogenetic variations in the carapace of Chelonia, H. Gadow. Dr. Willey had brought home twenty very young specimens of the Loggerhead Turtle, *Thalassochelys caretta*. This material has been supplemented by the examination of the specimens in the British Museum and the Cambridge Museum of Zoology. In all fifty-six specimens have been examined, consisting of forty-one very young, and others ranging from three inches to the full-grown turtle of about four feet in length of shell. This species exhibits a great amount of variation in the number and size of the epidermal shields which cover the shell. The variations are most numerous in the young, least so in the adult. They can be reduced to a system, each variation representing an atavistic or phyletically older stage, the greater number of shields being the more primitive. The reduction in numbers proceeds in a definite way, until the normal number (namely that which is found in most adult specimens) is reached. Hence the term "orthogenetic variation."—Some points in the morphology of the Enteropneusta, A. Willey. The body-wall of Enteropneusta is characterised externally by annulations determined by the zonary disposition of epidermal glands and separated by interannular grooves. The potentialities of these structures are indicated by the external liver-saccules of Ptychoderidae, which are enlargements of the annulations; and by the dermal pits of Spengelia, which are intergonadial depressions of the interannular grooves. In the Enteropneusta and in the Cephalochorda the gonads are more or less coextensive with the gill-clefts, both being primarily unlimited in number. A theory of gill-slits was developed, according to which gill-slits arose in the interannular depressions, while the gonads were disposed in zones corresponding with the epidermal annulations. The primary function of the gill-slits was the oxygenation of the gonads, their secondary functions being the respiration of the individual. In most cases the gonads have been secondarily emancipated from the gill-clefts in correlation with the elaboration of the vascular system. In the author's opinion the evidence in support of this theory is overwhelming. A collective name, Branchiotrema, was introduced to include all animals which possess gill-slits, whether in the adult or in the embryo.—On *Lepidodendron* from the Calciferous Sandstone of Scotland, A. C. Seward and A. W. Hill. A description was given of the anatomy of an unusually well preserved stem of *Lepidodendron Wunschianum* recently found in a railway cutting at Dalmeny in Linlithgowshire. The stem measures nearly 40 cm. in diameter, the outer bark is well-preserved, but the more delicate middle cortex was destroyed before petrification; the innermost cortex and the central cylinder show remarkably perfect structure. One of the important characters noticed in the stem was the structure of the leaf-trace bundles; these consist of a small strand of xylem more or less completely surrounded by radially disposed rows of secondary elements. The presence of numerous secretory canals in the outer cortex or phelloderm was also referred to as a feature of some interest.

PARIS.

Academy of Sciences, November 21.—M. Wolf in the chair.—On some relations between luminous and chemical energy, and on the displacements between oxygen and the halogen elements, by M. Berthelot. The decomposition of iodic acid into its elements is a reaction which cannot be reversed by sunlight, either dry or in presence of water. The reaction between bromine and water is almost unmeasurable in the dark, but becomes sensible in sunlight. The reverse reaction between hydrobromic acid and oxygen can be shown to take place in sunlight to a small extent.—On the atomicity of boron, by Sir Edward Frankland. Some remarks on the substance described by M. Copaux in the last number of the *Comptes rendus*, arising from the reaction between sodium ethylate and ethyl borate. The formula $(C_2H_5)(ONa).B(OC_2H_5)_3$ would appear to be more probable than that suggested by M. Copaux.—On observations of the Leonid meteors, made from a balloon during the night of November 13 to 14, by M. J. Janssen. Although, by reason of the cloudy state of the sky, the night of November 13 was very unfavourable for observations from the ground, good results were obtained from a balloon at a height of 150 to 200 metres, about twenty-five Leonids being noted.—On the determination of the latitude of the Observatory of Paris by the methods of M. Loewy, by MM. H. Renan, J. Perchot, and W. Ebert. The method used has the advantage over the usual one of measuring the superior and inferior culminations of circumpolar stars of giving results based on night observations only.—Observations of the planet DQ (433), made at the Observatory of Paris, by M. G. Bigourdan.—Elements of the planet DQ (433), calculated by M. G. Fayet.—Observations of Leonids, made on November 14 at the Observatory of Lyons, by M. Ch. André.—On differential systems of which the integration can be reduced to that of total differential equations, by M. Riquier.—An experiment reproducing the properties of magnets by means of combinations of vortices, in air or in water, by M. Ch. Weyher. The bars representing the magnets have a wooden axis, upon which are fastened strong paper vanes along its whole length. A similar bar set in rotation attracts or repels the first, according as the directions of rotation are the same or opposite; the two showing the neutral zone and other properties of magnets.—On the induction machines used as generators or receivers of alternating currents, either simple or polyphase, by M. Maurice Leblanc.—Characterisation of diabetic sugar in urine, by M. Le Goff. The sugar was isolated from the urine by filtration and evaporation in a vacuum to a syrup, from which crystals separated after a fortnight. These crystals were washed with alcohol, then dissolved and treated with animal charcoal, and crystallised out slowly *in vacuo*. The sugar thus obtained had the composition $C_6H_{12}O_6 + \frac{1}{2}H_2O$, for which the rotatory power was $(\alpha)_D = +49^\circ{\cdot}46$. The osazone formed needles, melting at 230°, and oxidation yielded gluconic acid, $(\alpha)_D = +6^\circ{\cdot}53$. These results show that the sugar present in diabetic urine is undoubtedly *d*-glucose.—The utilisation of the phosphoric acid dissolved in the waters of the soil by plants, by M. Th. Schloesing, jun. In sterilised soil, which has been treated with solutions containing all the elements necessary for plant growth except phosphoric acid, plants will not develop naturally, but in presence of solutions containing in addition quantities of phosphates of the order of those contained in arable earth, the plants flourish.—General conclusions on humic coals, by M. C. Eg. Bertrand.—On the constitution of peat, by M. B. Renault. The black peat studied consists of microscopical débris of plants arising from the tougher tissues, such as cuticle, spores, and pollen grains, the other tissues having generally disappeared under diverse influences, especially microbial action. The wood found in peat bogs has undergone a profound modification; its tissue is permeated with the mycelium of microscopic fungi, and numerous micrococci are present.—Artificial production of pearls in the *Haliotis*, by M. Louis Boutan. By the introduction of foreign bodies into *Haliotis*, true pearls can be produced.—On a method of colouring protoplasm by bacterial pigments, by M. L. Matruchot. By growing together on the same medium, a chromogenic bacterium (violet pigment) and a filamentous fungus, an impregnation of the protoplasm of the latter by the pigment can be obtained, and as the colouring matter is selective and is fixed only by a part of the protoplasm, this treatment constitutes a true method of coloration allowing the study of the structure of living protoplasm. This method has been applied by the author to a species of *Mortierella*.—On the black phosphates of the Pyrenees, by M. David Levat. A description of the nature of the deposit, and analyses of the phosphatic nodules. The nodules are black, resembling anthracite in appearance, and consist of nearly pure calcium phosphate.—On the presence of fossil layers containing species of *Physa* and *Limnoea* in the Lower Eocene of Corbières, by M. A. Bresson.—On the parallelism of the Urgonian limestones with the Cephalopod layers in the Dephino-rhodanian region, by M. Victor Paquier.

AMSTERDAM.

Royal Academy of Sciences, October 29.—Prof. van de Sande Bakhuyzen in the chair.—Prof. D. J. Korteweg made some remarks upon the progress in the preparation for the International Catalogue since the Conference of July 1896. Special mention was made of some of the resolutions passed in the Conference of October 11 to 13.—Prof. Winkler made a communication entitled "Attention and Respiration," which will be inserted in the Report of the meeting.—Prof. van der

Waals gave a simple deduction for the formula (p, v, t) for substances whose molecules are compound, and must be considered small bodies of a certain magnitude. In this deduction, which is entirely founded upon the virial equation, a first approximation is given for the variation of the co-volume, and the way is pointed out in which a second approximation might be calculated.—Prof. Lobry de Bruyn made a communication, on behalf of Dr. Steger and himself, concerning the rate of substitution of a nitro-group by an oxyalkyl in accordance with the equation:

$$C_6H_4(NO_2)^2 + NaOCH_3(C_2H_5) = C_6H_4NO_2.OCH_3(C_2H_5) + NaNO_2.$$

It was proved that the nitro-group is more rapidly substituted in paradinitrobenzol than in orthodinitrobenzol, and that sodium methylate acts more slowly than sodium ethylate. It was also determined that the decrease of concentration does not raise the reaction constant, a result opposed to that arrived at by Hecht, Conrad and Brückner as to the formation of ether from alkyl iodide and alkoholate.—Prof. Behrens made a communication concerning some anomalies in Mendeléeff's system, which will also be inserted in the Report of the meeting.—Prof. Hoogewerff and Dr. van Dorp found that the imides of bibasic acids, when heated with methylalcohol, are in many cases transformed into the ethers of amidic acids.—Prof. Kamerlingh Onnes described an open manometer of reduced height, placed in the Leiden Laboratory. The apparatus is composed of fifteen partial manometers of 4 atm., arranged in series. To obtain the requisite pressure in the connecting tubes between the consecutive monometers, compressed gas is introduced into them by needle cocks from a high-pressure cylinder. The apparatus ranges to 60 atmospheres at once, and by two further steps 100 atm. may be reached with part of it.—Dr. Hoek made a communication, on behalf of Mr. M C. Dekhuyzen of Leiden, concerning crater-shaped blood corpuscles (chromocraters). The observations described give ground for the opinion that the chromocrater is an ancestral inheritance from the worms, which has also been preserved in mammals and in man.—Prof. H. G. van de Sande Bakhuyzen presented a communication from Dr. E. F. van de Sande Bakhuyzen, entitled "Some observations on the 14-monthly movement of the terrestrial pole and on the length of its period."—Prof. van der Waals presented a paper on behalf of Mr. N. J. van der Lee, entitled "On the influence of pressure on the critical temperature of solution." Experiments were made with the mixture phenol-water, and the critical temperatures of solution appeared to rise by increased pressure. The rise was about 0·1° for 30 atm. In the case of this mixture theory points to a maximum in the line indicating the pressure of the vapour in contact with the liquid as function of the composition. This conclusion was confirmed by experiments.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 1.

LINNEAN SOCIETY, at 8.—On the Biology of *Agaricus velutipes*, Curt.: R. H. Biffen.—On the Gastric Glands of the Marsupialia: Jas. Johnstone.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—The Oxidation of Polyhydric Alcohols in presence of Iron: H. J. H. Fenton and H. Jackson.

FRIDAY, DECEMBER 2.

GEOLOGISTS' ASSOCIATION, at 8.—Contributions to the Geology of the Thame Valley: A. M. Davies.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Sunlight Gold-bearing Reef, Lydenberg, Transvaal: Charles Benjamin Saner.

QUEKETT MICROSCOPICAL CLUB, at 8.

MONDAY, DECEMBER 5.

SOCIETY OF ARTS, at 8.—Acetylene: Prof. Vivian B. Lewes.

IMPERIAL INSTITUTE, at 8.30.—A National Photographic Record: Sir Benjamin Stone.

VICTORIA INSTITUTE, at 4.30.—Recent Discoveries on Babylonian Tablets: T. G. Pinches.

TUESDAY, DECEMBER 6.

SOCIETY OF ARTS, at 4.30.—The Yangtse Basin and the British Empire: Archibald Little.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—Exhibition of Ethnological Photographs, with Remarks: Rev. H. N Hutchinson.—On the Caves, Shell-Mounds, and Stone Implements of South Africa: George Leith.—On Worked Flints from Griqualand East: J. M. Frames.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: The Effect of Subsidence due to Coal-Workings upon Bridges and other Structures: Stanley Robert Kay.——And, time permitting, Paper to be read with a view to discussion: The Ventilation of Tunnels and Buildings: Francis Fox.

RÖNTGEN SOCIETY, at 8.—A Discussion on Dermatitis, in relation to Röntgen Ray Work, will be introduced by Mr. Ernest Payne and Dr. Walsh.

ROYAL VICTORIA HALL.—Photography in Colours: Child Bayley.

WEDNESDAY, DECEMBER 7.

SOCIETY OF ARTS, at 8.—Egypt and the Sudan, in 1897 and 1898: W. T. Maud.

GEOLOGICAL SOCIETY, at 8.—The Geological Structure of the Southern Malverns and the Adjacent Districts to the West: Prof. T. T. Groom.—The Permian Conglomerates of the Lower Severn Basin: W. W. King.

ENTOMOLOGICAL SOCIETY, at 8.

SOCIETY OF PUBLIC ANALYSTS, at 8.—The Use of the Micro-spectroscope, and the Methods of Detecting Blood in Chemical-Legal Investigations: A. H. Allen.

THURSDAY, DECEMBER 8.

ROYAL SOCIETY, at 4.30.

MATHEMATICAL SOCIETY, at 8.—On Groups of the Order p^aq^β: Prof. Burnside, F.R.S.—On Simultaneous Partial Differential Equations: J. E. Campbell.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Improvement in Magnetic Space Telegraphy: Prof. Oliver Lodge, F R.S.——And, if time permit: Telegraphy by Magnetic Induction: Sydney Everard.

FRIDAY, DECEMBER 9.

PHYSICAL SOCIETY, at 5.—Longitudinal Vibrations in Solid and Hollow Cylinders; Dr. C. Chree, F.R.S.—On the Thermal Properties of Normal Pentane: J. Rose-Innes and Dr. Sydney Young F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 8.

MALACOLOGICAL SOCIETY, at 8.

BOOKS and PAMPHLETS RECEIVED.

BOOKS.—Nichelatura: I. Ghersi (Milano, Hoepli).—Colorazione e Decorazione dei Metalli: I. Ghersi (Milano, Hoepli).—L'Alluminio: Dr. C. Formenti (Milano, Hoepli).—Ricettario Industriale: I. Ghersi (Milano, Hoepli).—Journal and Proceedings of the Royal Society of New South Wales, 1897. Vol xxxi. (Sydney).—Schantung und Deutsch China: E. von Hesse-Wartegg (Leipzig, Weber).—Congrès National d'Hygiène et de Climatologie Medicale de la Belgique et du Congo, seconde partie, Congo (Bruxelles, Hayez).—Natalité et Démocratie: A. Dumont (Paris, Schleicher).—Human Immortality: Prof. W. James (Constable).—A New Astronomy: Prof. D. P. Todd (Low).—Quaero [some questions in Matter, Energy, Intelligence, and Evolution]: Dr. J. H. Keeling (Taylor).—Illustrated Catalogue of Balances and Weights, &c., Manufactured and Imported by W. and J. George, Ltd. (George).—University College, Sheffield, Calendar, Session 1898–99 (Sheffield).—Repetitorium der Zoologie: Prof. K. Eckstein, Zweite Auflage (Leipzig, Engelmann).—Grundriss der Psychologie: W. Wundt, Dritte Auflage (Leipzig, Engelmann).

PAMPHLETS.—Les Bases de la Météorologie Dynamique: Dr. Hildebrandsson and L. T. de Bort, 1re Livn (Paris, Gauthier-Villars).—Observations et Mesures de la Suède, i. and ii. (Upsala).—Das Mittelenglische Gedicht, the Boke of Cupide, Kritische Ausgabe: Dr. E. Vollmer (Berlin, Ebering).—Incubators and Chicken-Rearing Appliances (Cassell).

PHYSIOLOGICAL SELECTION.

Darwin, and after Darwin. By Dr. G. J. Romanes. Pp. viii + 181. (London: Longmans, Green, and Co., 1897.)

THIS third volume concludes the series "Darwin, and after Darwin" of which G. J. Romanes had published the first volume and had planned and mostly written the remaining two, at the time of his death. This volume, as well as the second, has been prepared for the press under the able editorship of Prof. Lloyd Morgan, who has performed a difficult task with conspicuous success. In a brief preface we are told that the first two chapters and the last were in type at the time of the author's death, and remain practically unchanged; while the editor is responsible for the selection and arrangement of the remaining three. The Appendices A and B, bearing upon the controversy with Alfred Russel Wallace, "remain in accordance with the author's expressed injunctions." The frontispiece to the volume is a portrait of the Rev. J. T. Gulick, whose most interesting researches into the variation of the land-shells of the Sandwich Islands led him, independently, to a theory closely similar to that of "physiological selection."

Of all the three volumes of this series, this possesses the greatest personal interest; for it is devoted to the exposition and discussion of the evidence for and against the much debated hypothesis of physiological selection, which, although never widely accepted, always remained dear to its creator. The present volume, which possesses many advantages over the original account of the hypothesis published in the Linnean Society's Journal, will do much to enable biologists clearly to grasp the author's meaning.

The two first chapters deal with "isolation" in general, a principle which was given a position of the utmost importance by the author, who regarded not only his own physiological selection, but natural selection itself as a special form of isolation. The third, fourth and fifth chapters deal with "physiological selection" and its evidences; the sixth again returns to "isolation" as a factor in "organic evolution," and also contains the "general conclusions." Appendix A contains Mr. Gulick's criticism of Mr. Wallace's views on physiological selection; B, an examination by Mr. Fletcher Moulton of a calculation by Mr. Wallace on the same subject; C, "some extracts from the author's note-book."

In the discussion of isolation the author first distinguishes between *indiscriminate* isolation such as would be produced by some sudden geographical change separating the individuals of a species into two detachments, and *discriminate* isolation such as would be caused by a part of the species seeking some new area, or some different habitat on the same area. While Mr. Gulick recognised this distinction under the terms "separate breeding" and "segregate breeding," the author suggests "apogamy" and "homogamy." He says, moreover, "with the exception of Mr. Gulick, I cannot find that any other writer has hitherto stated this supremely important distinction between isolation as discriminate and indiscriminate." But the classes of facts to which he alludes are distinguished by every writer and thinker on evolution: the only difference being that the author is peculiar in making isolation the basis of his classification. Other writers have used the term "isolation" for the cases in which separation is the primary and essential factor, viz. for "indiscriminate isolation" only; "discriminate isolation" they have classified as "natural selection" or as "Lamarckian evolution," as the case may be, the separation being regarded as a secondary result.

The whole discussion of isolation in the exalted position in which it is placed by the author ("the whole theory of organic evolution becomes neither more nor less than . . . a theory of the causes which lead to discriminate isolation," p. 6) is interesting and suggestive, and a large part of it convincing. It is also for the most part clear and lucid in treatment, although sentences occur which seem unnecessarily to demand the strained attention of the reader. Thus after arguing that diversification of character is *promoted* but never *originated* by natural selection, the author concludes, in the following complicated passage:

> "Therefore the change must in all cases have been due, in the first instance, to some other form of isolation than the superadded form which afterwards arose from superior fitness in the possession of superior benefit—although, so long as the prior form of isolation endured, or continued to furnish the necessary condition to the co-operation of the survival of the fittest, survival of the fittest would have continued to increase the divergence of character in as many ramifying lines as there were thus given to its action separate cases of isolation by other means" (p. 32).

The ideas sought to be conveyed in this quotation are not difficult of comprehension, but the form is such that they become intelligible only with effort.

Physiological selection is defined by the author at the opening of the third chapter as "that form of isolation which arises in consequence of mutual infertility between the members of any group of organisms and those of all other similarly isolated groups occupying simultaneously the same area." The two great difficulties in the way of natural selection as a sufficient explanation of the origin of species are held to be the difference between domesticated varieties and natural species in respect to cross fertility, and "the fact that natural selection cannot possibly give rise to polytypic as distinguished from monotypic evolution." The former difficulty has long been felt, and it was the great logical flaw which always prevented Huxley from declaring his entire conviction in the soundness of the theory. The author is certainly right in claiming for physiological selection that it would tend towards the removal of this difficulty. As to the second difficulty the majority of Darwinians will not be convinced by the author's reasons for thus limiting the power and scope of natural selection.

The conception of physiological selection—the idea that the differentiation of species begins with infertility instead of ending with it—is here shown to have arisen independently in many minds, having been first mentioned by Belt (1874), then by Catchpool (1884), Romanes (1886), and Gulick (1887).

To the present writer it has always appeared that the suggestion is an extremely interesting and ingenious one, the chief objection being the immense difficulty in proving that it actually exists or has ever existed as an operative principle. If it exists, then much that is claimed for it would follow. We know that geographical isolation is followed by differentiation, and many evolutionists are prepared to admit that some of the minor differences thus produced may be independent of natural selection. Most naturalists would probably be inclined thus to explain the differences between the land-shells of adjacent valleys in the Sandwich Islands as described by Gulick. Those who believe in physiological selection consider that what is here brought about through the prevention of interbreeding by geographical barriers, is produced on continuously peopled areas by the physiological barrier of infertility.

This conclusion is capable of being tested to a certain extent by an investigation of the degree of infertility between species which are known to have been produced in the former manner and those (of approximately equal differentiation) which are believed to have been produced in the latter. Apart from its application to the present controversy such an inquiry would be of great interest in itself.

The results of such an investigation would be far more convincing than the elaborate and often very ingenious arguments of the writer, many of which are capable of an immediate and satisfactory answer. For instance on pp. 48, 49, he asks how it is that the reproductive system is always affected "in the same peculiar way," viz. so as to produce mutual sterility, between different species of all kinds, animal and vegetable, separated by morphological differences of infinite variety. It is evident that he regards this question as unanswerable except on the view that the infertility is the invariable precursor and condition of the differentiation. But the facts can readily be explained otherwise. Mutual fertility depends upon the exact relotionship of two extraordinarily complex bodies, the germ-cells of male and female; it depends upon a reciprocal adjustment of almost infinite precision. Single individual variations receding from the necessary precision continually arise, but are infallibly exterminated. Such variations are not to be looked upon as due to a single and uniform change in the complex material of the germ-substance. The opposite point of view is the truer: mutual fertility is due to a single and uniform constitution rigidly kept within the narrowest limits, while a minute change of constitution *in any direction* means infertility. Mutual infertility is, in fact, but the single external indication of numberless changes of constitution. The necessary precision of adjustment of the male to the female germ-substance is only kept up in the species by unremitting selection, and there is no cause for surprise that it should cease when selection is no longer forthcoming for its support. These considerations seem at first sight to indicate that mutual fertility between domestic breeds is a matter for greater wonder than the infertility between natural species. We cease to wonder, however, when we reflect upon the length of time which must have elapsed since the separation of natural species such as the horse and ass, which are nevertheless fertile when crossed, although their hybrid progeny is sterile. Since this is the case the mutual fertility of our modern domestic races, so far as it has been proved to exist, is only what we should have been led to expect. In this relationship the present writer has often considered that further experiments upon these latter would be of great value, especially in the case of races in which the morphological differences have been carried to a very high degree—so much so, indeed, that artificial fertilisation would probably be necessary.

The argument which has been met in the last paragraph is evidently one on which the greatest stress is laid. Thus we again read on p. 51 of "this one peculiarity of the reproductive system," viz. mutual infertility; and on pp. 52, 53, it is made a chief support for the hypothesis of physiological selection, a good brief account of which will here be found. Throughout the whole work we meet with the same insistence on "this constant primary distinction," "the same peculiar change," &c., as one main foundation for the hypothesis.

If space had permitted, many other interesting points raised in this volume might have been discussed. It is of great service to the student of evolution that the hypothesis of physiological selection, the arguments for it and evidence which supports it, should have been brought forward in so readable a form. The work is printed in pleasant type, and has been so carefully seen through the press, that there are practically no printer's mistakes.

E. B. P.

THE THEORY OF GROUPS.

Theory of Groups of Finite Order. By W. Burnside, M.A., F.R.S. Pp. xvi + 388. (Cambridge University Press, 1897.)

THE theory of groups of finite order is one to which in very recent times the attention of mathematicians has again and again been directed. Until a little time ago any one who wished to become acquainted with the elements of the theory would have been referred to J. Serret's "Algebra," to C. Jordan's comprehensive "Traité des substitutions," and to E. Netto's introductory work on the same subject. No one who takes account of the time at which it was written will wish to depreciate the merits of the first of these, but the chapters dealing with groups consist of a series of extracts reproduced from the original memoirs of the masters to whom we owe this branch of mathematics: these extracts are chosen with all the knowledge of an expert as to what should be chosen, but are not worked up. C. Jordan brings together an overpowering wealth of material, which for the most part has its origin in his own researches; but there can scarcely ever have been any one who would be in a position to work through the treatise from beginning to end; or who could without guidance from some other source separate the fundamental portions from the mass of detail. Lastly, Netto's book on substitutions is now fifteen years old; it still forms a useful introduction to the subject, but it goes no further than that.

The most modern treatises on algebra mete out varying treatment to the theory of groups. Netto leaves it on one side altogether; Drach makes the interesting experiment of attempting to build up the elements of

algebra by a consecutive formulation of Kronecker's abstractions without using the notion of a limit, and restricts himself in the process to those parts of the group-theory that are necessary for his purpose; Vogt provides for French readers an equivalent of what Netto, in his older book, and Netto's translators, Battaglini and Cole, had given to Germans, French, and English; in Weber's great treatise the theory appears as an important aspect, but still only an aspect, of the problem of algebra. For all these books the theory of groups is a means to an end, or rather to one of multifarious ends which it can be called upon to serve, viz. the algebraic solution of equations.

But in course of time the theory of groups has ever more and more emancipated itself from algebra, whose servant it originally was. Years ago Cayley threw out, though he did not develop, the fundamental idea that the notion of a group, in and for itself, is in no way bound up with permutations and substitutions, but arises whenever the effect of two operations performed successively upon an object is the same as that of a single operation of the same kind. In the general theory of groups thus founded, groups of finite order form a well-marked division. To bring together the great mass of single results yielded by exploring this division of the theory from different sides, to take a comprehensive view of them, and to exhibit them in a well-digested form, is the problem that has been attempted for the first time in the book before us, and it is solved in the happiest manner.

The author does not push abstraction to the point of banishing from his book all concrete methods of representation of groups. He frequently uses properties of groups of substitutions, in particular, not merely with a view to making results plain to intuition, but also for the deduction from them of properties of groups in the abstract. He himself asks the question why other particular methods of representation of a group, *e.g.* by means of homogeneous linear transformations, are not employed in a similar way, and he answers it, as I think rightly, in the words "that, while in the present state of our knowledge, many results in the pure theory are arrived at most readily by dealing with properties of substitution groups, it would be difficult to find a result that could be most directly obtained by the consideration of groups of linear transformations."

Believing that familiarity with symbolical calculations concerning interchanges of letters is not to be assumed on the part of his countrymen, the author gives a sketch of this theory in a short first chapter. The second chapter begins with Cayley's abstract definition, cited above, and carries the development of the general properties of a group as far as Dyck's theorem to the effect that every group of finite order N can be represented as a group of interchanges of N symbols. The third chapter develops the notions: sub-group, self-conjugate sub-group, simple group, isomorphism, factor groups. Then follow in chapters four and five special investigations relating to Abelian groups and to groups whose order is a prime number; in the latter the author has placed a series of results of his own researches. The sixth chapter brings us back with Sylow's theorem to the general theory, and the pivot of the theory is found, in chapter seven, in the theorems on the composition-series of a group. The three following chapters are especially concerned with groups of substitutions, with the questions of their transitivity and primitivity; in addition to the general theorems, they contain a great number of completed researches on special groups and types of groups; some of these are of intrinsic interest, and others serve as vivid illustrations of the general theory. The eleventh chapter treats of the isomorphism of a group with itself on the lines followed by Hölder and Frobenius. In the twelfth and thirteenth chapters is explained the method of representation of a group which was developed in a general manner by Dyck, viz. the representation by means of geometrical transformations of a surface divided into regions, and especially by the transformations effected by linear relations between complex variables. An older method, due to Cayley, of representation by coloured diagrams leads in simple cases to results easier to appreciate at a glance; this method also is here expounded and illustrated by a beautifully executed coloured plate. The fourteenth chapter treats of the representation of a group by means of systems of linear congruences. There is a certain incongruity in the fact that while this is inserted, the representation by means of systems of linear equations is omitted; but the theory of this method would by itself furnish material for a second book as large as the one before us. Perhaps the author will some day give us such a book. On the other hand we find here the extension of the theory named to congruences holding among Galois' imaginaries. This was cultivated in his time by E. Mathieu, and has been taken up recently by E. H. Moore and the author of this treatise, in whose hands it has led, among other remarkable results, to the knowledge of a new series of types of finite groups. Finally the last chapter gives an account of the most modern enumerations of types of groups, in particular of simple groups of an order which can be expressed in a prescribed manner as a product of primes.

The author has not attempted to give historical references concerning the discovery of the older theorems; but for the more modern literature, of about the last twenty years, and right up to the time of publication, his references are full and trustworthy.

In respect of the completeness and exactness of its matter, the work fills in a very acceptable manner a gap in the literature of mathematics, and not merely of mathematics in England. It brings to the special subject a great wealth of material for the widening and deepening of knowledge; while at the same time beginners, under expert guidance, will be able to make a profitable use of it.

H. Burkhardt.

OUR BOOK SHELF.

Radiation: an Elementary Treatise on Electro-magnetic Radiation, and on Rontgen and Cathode Rays. By H. H. Francis Hyndman, B.Sc. (Lond.). With a Preface by Prof. Silvanus P. Thompson, D.Sc., F.R.S. Pp. xviii + 307. (London: Swan Sonnenschein and Co., Ltd. New York: The Macmillan Co., 1898.)

The author considers chiefly those portions of the subject which are somewhat neglected in most books, and in addition deals with the results of some of the

more recent investigations. Brief outlines are, however, given of those parts that are not especially treated, in order to maintain continuity and allow of a direct comparison of the properties of the different radiations. Many references are given to original sources, which enable the reader to extend more readily the narrow limits of the book.

The treatise contains an account of a large amount of interesting work, but it can scarcely be expected that one not perfectly familiar with the subject can follow the ideas so briefly expressed in many places.

Throughout the volume we are confronted with a considerable number of misleading and erroneous statements, the nature of which can be seen from a few examples. For instance, on p. 255 it is stated :—"That the rays do not themselves act as conductors seems proved, for they can pass between bodies of very different potentials if these are not already connected by lines of force." Any comment on this is superfluous.

On p. 198 we read :—"The cathode rays possess the same power as the ultra-violet and the X-rays, of causing those gases which they traverse to become conductors of electricity." All careful experiments, however, show that ultra-violet light in traversing a gas does not produce any conductivity.

Again, on p. 259 it is stated that the charge carried by the ions in X-ray conduction can be calculated from the values of the saturation current and the time required for the conductivity of the gas to sink to half of its value. Such a calculation is not possible.

On p. 254, in regard to conduction produced by the passage of X-rays through bodies, we read that "paraffin, wax, sulphur, ebonite, mica, and all gases become conductors." It is now generally believed, however, that solid insulators are not made to conduct by the rays, and the author ignores this side of the question.

Strict accuracy in the facts presented is an essential of every scientific treatise, as the harm produced by the inception of erroneous ideas cannot be over-estimated.

J. Z.

Four-footed Americans and their Kin. By Mabel Osgood Wright. Pp. xv + 432 ; illustrated. (London : Macmillan and Co., Ltd. New York : The Macmillan Company, 1898.)

WHATEVER difference of opinion may obtain as to whether the title of this little volume is the best that could have been found, or whether the "Mr. Barlow" style of "Sanford and Merton" is the most suitable for popular natural history, there can be no hesitation in according the highest praise to the exquisite illustrations which form its most attractive feature. In addition to being in every way artistic productions these, so far as we can judge, are absolutely life-like ; portraying the animals not only among their natural surroundings, but also in characteristic attitudes. Where none are bad, and all attain a high standard of excellence, it is almost invidious to make a selection ; but two of the illustrations which especially strike our fancy are the wood-hare on p. 141, and the little striped skunk on p. 181. It is rare, indeed, to meet with illustrations of such a high class, and these alone ought to give the book a large sale ; while the artist, Mr. E. S. Thompson, ought to obtain a world-wide reputation as a delineator of animal life.

But it is not on the illustrations alone that the book has to depend for popularity ; as, allowing for certain peculiarities in the style, the descriptions of the habits of the various animals mentioned are for the most part well written and entertaining. A classified synopsis at the end gives a clue to the identification of the species described ; and in this connection it is important to notice that in nearly all cases the author is thoroughly up to date as regards nomenclature. As changes in nomenclature have been necessary, it is most desirable that they should be adopted by popular writers. We must, however, take leave to object to the title of "Beef or Meat Family" for the *Bovidae*, as also of "Antelope Family" for the Prongbuck, and of "Leapers" for the *Leporidae*. Since, too, the *Viverridae* are conspicuous by their absence in America, the misnomer of "Civet-cat" is decidedly objectionable for the Cacomistle (*Bassariscus*), whose inclusion among the "Cousins of Cats" is scarcely warranted by the facts. As a Christmas present to all young persons interested in animals, the work may be confidently recommended.

R. L.

Electricity made Easy, by Simple Language and Copious Illustration. By Edwin J. Houston, Ph.D., and Arthur E. Kennelly, Sc.D. Pp. 348. (London : Swan Sonnenschein and Co., Ltd., 1898.)

SIMPLE descriptions and explanations of electrical appliances met in every-day life are given in this volume. Facts with regard to the nature and functions of electric mains, the distribution of currents, generating stations, the principles of incandescent and arc lighting, measurement of electric supply, electric bells, telegraphy, telephones, and other things concerned in the production and uses of electricity are stated in the simplest of words. Illustrations are given of the external and internal appearance of many of the appliances described. These pictures are, perhaps, a trifle too numerous, for they tend to give the volume the character of a catalogue of electric fittings.

The comparison of the flow of water with the flow of electricity is a useful one ; but there is a danger that the reader will carry the analogy too far. On p. 30, for instance, we read that electricity "flows through wires very much like water or gas flows through pipes, but flows through a solid wire as readily as through a tubular wire of the same weight." Brief statements of this kind are frequently the cause of serious misconceptions as to the nature of electricity.

Differential and Integral Calculus for Technical Schools and Colleges. By P. A. Lambert, M.A., Assistant-Professor of Mathematics, Lehigh University. Pp. x + 245. (New York : The Macmillan Company. London : Macmillan and Co., Ltd., 1898.)

THE first hundred pages of this book are occupied with the differentiation and integration of simple algebraic functions, including easy applications to geometry, and here and there a mechanical problem is set amongst the examples.

Then come chapters involving trigonometrical functions, and logarithmic and exponential functions, followed by a chapter containing applications to mass centres and moments of inertia. The next two chapters deal with expansions and applications of Taylor's theorem, and the last forty pages of the work are devoted to an outline discussion of certain simple classes of differential equations.

There are some good features in the book considered as an introductory text-book for ordinary school use where a good deal of supplementary oral teaching would be given. Thus the statement of methods and the proofs, or indications of proof, are clearly worded ; the examples are easy and straightforward, and in two or three cases distinctly fresh illustrations appear.

But the general treatment is very superficial : far too much ground is covered ; there is an appearance of easy progress produced by the avoiding of the real difficulties which occur in the practical applications of the calculus. In fact, it is quite misleading to describe the work as specially adapted for technical schools and colleges. No instructor of an English technical class would consider this handbook an adequate introduction to the application of the calculus to physics or engineering.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Range of the Garefowl (Alca impennis).

IN 1856 the late Dr. Gray obtained for the British Museum an example of this extinct species from the collection of the late Prof. van Lidth de Jeude of Utrecht, and for some reason unknown to me had the locality "Labrador" painted on its stand. As I had been informed with certainty by the late Prof. J. T. Reinhardt that this specimen was one of those sent to Copenhagen from Iceland, I corrected the error in *The Natural History Review* of October 1865 (vol. v. p. 473, note), and the correction has since been generally accepted. It is therefore with some regret that I find the old error repeated in the recently published volume of the "Catalogue of the Birds in the British Museum" (vol. xxvi. p. 564), and the error is rather a serious one in the absence of evidence of the species having inhabited the coast of Labrador, as well as that of any skin of proved Transatlantic origin. I may also mention that on the same page of the "Catalogue," the date of Bullock's Orcadian specimen is wrongly given as 1812 instead of 1813.

ALFRED NEWTON.

Magdalene College, Cambridge, December 3.

Asymmetry and Vitalism.

THIS must be my last word on this subject, and it is only written because Prof. Japp asks me to correct him if I consider him wrong in his interpretation of my illustration of the separation of tetrahedral atoms. I apologise to him as a chemist if I used the word "compound" where I ought to have used "substance" or "mixture," although it seems to me Messrs. Kipling and Pope use the word compound in a perilously like sense in the eighth paragraph of their letter. The use of the word has nothing to do with the main argument, the chance production of the optically active "mixture," and then the production from the "mixture" of the optically active "compound" with only one enantiomorph. By the by, will Prof. Japp guarantee that all vital optically active substances are "compounds" in this sense, and not largely preponderating "mixtures"? I only put the question, rather irresponsibly in passing, owing to something a distinguished biologist let fall in my presence the other day. I am quite prepared to be told that this is as well demonstrated as the law of gravity. Now as to my illustration, I was certainly thinking of a spin from rest so that the tetrahedra start with an impulse relative to the fluid and further experience its resistance relative to their motion. Let us take the *simplest* possible case for an example. Suppose Z′ somewhat larger than Y′, both considerably larger than X′ and H negligible to a first approximation. Then I should expect Y′ to set itself nearly in the wake of Z′, and X′ to turn in towards the axis. Thus Z′, Y′, X′ would be in a plane perpendicular to the axis; this would bring H above for one type of tetrahedron and below for the other type, or we have differentiated the positions of right- and left-handed tetrahedra. However, I do not lay stress on the illustration, for whatever we do now to separate left- and right-handed tetrahedra, I take will be asymmetrical relative to the sense of the original spin, and accordingly if I am correct, I am only inventing a clumsy illustration of non-vital asymmetric force, of which Prof. Fitzgerald has already given a much better illustration in the earth's rotation. Will any physicist having the apparatus at his disposal kindly spin with great but *irregular* speed a couple of tetrahedra in a viscous fluid, the axis of the churn being horizontal? The balls at the angles of the tetrahedra, being arranged right- and left-handed and of masses somewhat as above, we should be able to settle whether a differentiation of position would or would not take place. I should not be surprised to hear that the two tetrahedra moved to opposite ends of the churn.

KARL PEARSON.

A Shag's Meal.

THE following observation on the habits of the shag (*Phalacrocorax graculus*), which frequents our coasts, is probably of interest in itself and not without bearing on the subject-matter of Mr. Lowe's letter (November 24)

On August 15 last, when at anchor in Wicklow harbour, in the course of a cruise, we noticed a shag alight upon the water at a short distance from our yacht. It was a very calm, bright day. What follows occurred within a distance of a cable's length or thereabouts of our boat; and as I observed the proceedings throughout by the help of a powerful "triëder binocle" (× 9) of Goerz, and my companion, Dr. H. H. Dixon, possesses unusually keen sight and closely followed the events, there is no doubt as to the reality of what is here recorded.

The shag, after swimming about for a little, dived once or twice—apparently fruitlessly—but finally appeared with a large eel in his beak. The eel was big and strong, and twisted into the form of a figure 8, evidently an awkward morsel. The bird kept snapping and shifting it in his beak, till at length with a few violent gulps it swallowed the eel, the latter evidently going down alive. It was to be inferred, in fact, that the shag was not happy with so large a live eel in his crop, for he swam restlessly about, twisting and stretching his neck incessantly. Presently he dived again, was down perhaps twenty seconds, and came up with an eel as large as the first one. This writhed and twisted like its predecessor, and, after much snapping, finally suffered the same fate. The same uneasiness was displayed by the bird, and the bird once more dived.

Dixon and I were expressing some surprise at the rapidity with which our friend had caught the two eels, and also at his very considerable capacity to hold two such large eels—certainly not less than 15 inches long each—when the bird reappeared bearing a third eel, as big as its predecessors and engaged in the same violent resistance. The same snapping, same gulping, same uneasiness and down for a dive once again! This was the third eel.

While we were taking sympathetic breaths with the insatiable shag, the latter reappeared—yet again with a 15-inch eel. Evidently the harbour was so full of 15-inch eels that a shag had only to dive to pick one up. It was also evident that no language could be too strong in which to condemn such unmeasured license. Four 15-inch eels—all swallowed alive—within the space of about four minutes!

But this was only the beginning, as will presently appear. The bird went down again almost immediately after the fourth. We determined to keep careful count and, if possible, get the measure, in eels, of a shag's capacity. Would he bring up another? Yes, there he was again with another 15-inch eel! A very vigorous eel—just like the others in size and appearance, and swallowed in the same manner, after about 30 seconds' resistance. This made five eels.

The question now arose as to what would be the end of this bird. Was he going to die the death of King Henry I. before our eyes? We called him King Henry to distinguish him from other shags.

To make a long story short, we counted *twelve* eels!—all stout 15-inchers. The twelfth seemed, perhaps, rather feebler than the others, but still it nearly got away. For King Henry dropped it in a too vigorous snap, and only recovered it by a prompt plunge forwards. H.R.H. now seemed to reflect that this last misadventure was a warning, swallowed his twelfth, and took flight; disappearing in an easterly direction whence he had come.

There is, of course, only one explanation of all this: the twelve eels were one and the same eel. To suppose the bird caught and devoured twelve eels of this size in as many minutes appears to us incredible. His final appearance as he flew astern of us betrayed no signs of surfeit. He would have had at least two pounds' weight of eel within had he really eaten twelve such eels.

The peculiar procedure of ejecting the prey under water appears very remarkable. Perhaps the head-downward attitude of diving is requisite to effect this.

Has this mode of weakening or playing with his prey been recorded of the shag (or, indeed, of any animal) previously?

Trinity College, Dublin, November 27. J. JOLY.

Periodic Tides.

ATTENTION has lately been called by Mr. H. C. Russell, of Sydney Observatory, to what may be termed a tide of short period, which he has detected in the enclosed harbour of Sydney.

Mr. Russell traces a connection between this interesting

phenomenon and certain meteorological conditions obtaining at a distance. Looking to the position of Sydney Harbour, it is only natural that we should expect to find the origin of these undulations in the open ocean; but experience of similar phenomena in another part of the world leads me to think that the cause, whether meteorological or not, must be sought nearer at hand.

My attention was first drawn to these curious fluctuations of sea level when golf playing on the low sands at the head of the landlocked harbour of Lemnos in the Greek archipelago, on August 9, 1895. I noticed that the current in the shallow streams communicating with the sea appeared to reverse at intervals of about a quarter of an hour, without any apparent cause. On returning to Malta I inquired if anything similar had been noticed there, and in consequence of information then received, I commenced some observations on my own account.

It is a matter of common knowledge to naval officers and others concerned, that the irregular variations of sea level in the Maltese inlets are at times sufficiently great to completely mask the slight lunar tide: and that the Port Officials are in the habit of insisting on a considerable margin of depth before permitting vessels to pass over the sills of the dry docks. These extra tidal variations of sea level have been ascribed to various causes, such as the direction and strength of prevailing winds, currents setting towards the mouth of the inlet, or to what is vaguely called the natural period of the harbour. My observations showed conclusively that there is at certain times in Malta Grand Harbour a perfectly regular ebb and flow with a period of twenty-three minutes; about the same period obtaining in Sydney Harbour, which Mr. Russell gives as twenty-six minutes.

My observations were made in the neighbourhood of Magazine Point, about two-thirds of the distance from the sea to the head of Valetta Harbour, the width across the harbour at this spot being little more than 300 yards. On May 7, 1896, the to-and-fro movement of the water was very remarkable, being continuous from 8 a.m. till 2 p.m. Between these hours the water in this part of the harbour rose and fell with the utmost regularity, the range being about 15 inches and the interval between successive high waters about twenty-three minutes. This variation of water level at the head of the harbour caused a strong current, which changed its direction every eleven or twelve minutes. The regular reversal of current was indicated in a remarkable manner by the behaviour of the spar buoy moored off Magazine Point. The weather during the morning was normally fine—that is to say, nearly calm inside the harbour, with a light but gradually increasing sea breeze outside.

The similarity in the period of the undulations observed at Sydney and at Malta suggests a common origin.

If, however, as Mr. Russell seems to think, the Sydney waves are due to the combined effect of wind and current influences exerted at a considerable distance, this similarity of period can be little more than a curious coincidence. Long period undulations, such as these under consideration, could hardly be originated by the wind and current systems of the Mediterranean, which, at the given time of the year, at all events, are feeble and comparatively local in their effects.

If, on the other hand, we for a moment suppose that the action of local currents and sea breezes, driving a head of water into the inlet, results in the establishment of regular oscillatory movements, is it probable that the "natural periods" of two harbours, differing so much in area as do those of Sydney and Valetta, would be so nearly equal?

Considerations such as these seem to indicate that the cause of these "short period" tides is one and the same, notwithstanding that they occur on opposite sides of the world and apparently under different conditions; and also that their real origin has not yet been ascertained.

Trustworthy observations in landlocked bays and harbours are still very much wanted, and it may be that until such are available in a greater degree than at present, the whole subject of tidal irregularity will remain more or less obscure.

In conclusion, sir, permit me to express the hope that you will afford space for the discussion of this interesting subject in your columns by those who are able to deal with it. In this way we may hope to ascertain whether any trace of earth movements occurring at short and regular intervals has been noticed near the localities and at the times mentioned: for it is just possible the true cause of these remarkable tides may be one hitherto unsuspected. ANTHONY S. THOMSON.

Concerning the Thermodynamic Correction for an Air Thermometer.

IT seems noteworthy not only that the theoretical investigation on this subject, given in Maxwell's "Theory of Heat" and Tait's "Heat," is fallacious, as has been pointed out by Mr. Rose-Innes in his letter which appeared in your issue of May 26, but that there is no indication in either of these text books that the result given is not in accordance with the experimental facts. The investigation in question, which is practically the same as that first given by Lord Kelvin before the experiments were performed, leads to the result that the cooling effect should be proportional to the difference of the logarithms of the pressures before and after passing the plug, instead of proportional to the difference of the pressures themselves, as was actually found to be the case; the discrepancy was, of course, noted by the experimenters. The methods used in all the theoretical discussions in Lord Kelvin's papers on this subject prior to the final one in Part iv. of the papers "On the Thermal Effects of Fluids in Motion," seem equally open to objection. The numerical results derived by the last method, which seems perfectly sound, were given apparently for the first time in the article "Heat" in the "Encyclopaedia Britannica"; the investigation and results are reproduced in Preston's "Theory of Heat," and substantially in Parker's "Thermodynamics." The correction obtained to the number representing the temperature of melting ice on the absolute scale by this method was + ·70, the previous methods giving in succession + ·83, − ·03 and + ·87; the uncorrected estimate finally used was also different from that taken at first. Science in Elementary Schools.

THE report on the teaching of science in elementary schools, drawn up by the British Association Committee, and published in your issue of November 24, is likely to be unintentionally misleading. The following paragraph leaves out of consideration an important modifying cause:—"It was remarked in the last report that the increased teaching of scientific specific subjects in the higher standards is the natural consequence of the greater attention paid to natural science in the lower part of the schools. The following table shows the correctness of this inference." [Then follows a table showing the gradual increase in the number of children examined in specific subjects.]

The Directory of the Science and Art Department for 1897 contained a new regulation to the effect that "no student may be registered for a grant for day attendance under the Department of Science and Art—except the grants for elementary drawing and manual instruction—whose name is on the register for day attendance under the English or Scotch Education Departments, or the National Board of Education, Ireland." The result of this has been that large classes under the Science and Art Department in such subjects as physiography and hygiene, composed of Standard VII. children in elementary schools, were discontinued; and, possibly with a view to replacing part of the grant thereby lost, specific subjects were taken up in connection with the Education Department. A considerable increase in the number of children taking specific subjects may be anticipated for the years 1897-8 and 1898-9, but the reason will scarcely be that put forward by the British Association Committee, but rather the new regulation from South Kensington. A. T. SIMMONS.

London.

THE new regulation of the Science and Art Department, quoted in Mr. Simmons's letter, was issued only in 1897: it was impossible, therefore, that the effect of it on the day schools could be shown in the tables that form part of our last report. The results may begin to show themselves in the report of next year, but only as an addition to the increase due to the greater attention still being paid to natural science in the lower part of the schools. It is to be hoped that this aggregate increase will be a large one; but it will evidently be very difficult to assign to each cause its proper proportion. J. H. GLADSTONE.

A Remedy for Bookworms.

IN NATURE, No. 1506, vol. lviii., of September 8, there is a review (p. 435) of a book, "Facts about Bookworms," by the Rev. J. F. X. O'Connor, S.J., which concludes by lamenting there is no panacea for these book pests.

Here, in tropical Queensland, I was much troubled by various borers, and "silver-fish"; but for the latter, which apparently only devour the glaze on paper, and paste, I found a new remedy in adding alum to paste, and keeping glazed writing paper in tin boxes.

For the former a solution of *corrosive sublimate and thymol in alcohol*, appears to be an effectual remedy, though probably it would require to be re-applied from time to time; but certainly all books dressed by me with this solution inside and outside the covers, have never been touched since.

The newspaper extract (paper and date unknown), from which I obtained the information, read as follows:—"Surgeon-General Bidie, in the *Fishing Gazette*, recommends a solution of corrosive sublimate and thymol as a perfect protection for books from the ravages of bookworms and other insect pests, having tested it in tropical countries where the termite and the larvae of innumerable creatures batten upon everything eatable, from door-posts to bottle corks."

I have certainly found this remedy thoroughly efficacious, and think it deserves to be more widely known.

J. EWEN DAVIDSON.

Branscombe, Mackay, Queensland, October 20.

The Properties of Liquid Mixtures.

IN the abstract of my communication to the Physical Society in connection with Mr. R. A. Lehfeldt's paper on the above subject (NATURE, December 1, p. 116), the most probable explanation of the fact that, when American petroleum is distilled, the benzene comes over at about 65° instead of 80°, is stated to be that "benzene and hexane behave, as regards distillation, *like miscible liquids*." This should read "*like partially miscible liquids*."

The two liquids are, in fact, miscible in all proportions, and the point is that, in certain respects, they behave as though they were only partially miscible.

SYDNEY YOUNG.

December 6.

The Mildness of the Season.

As an instance of the mildness of the season, I may state that on Sunday, November 27, I gathered five ripe strawberries out of my kitchen garden; and that a considerable number of strawberry plants still show signs of flower. Moreover, the leaves of several deciduous trees, such as peaches, lilacs, &c., which are planted in sheltered situations, are still perfectly green; whilst many others are only just beginning to assume their autumn tints. I have also gathered several rosebuds this morning.

In this part of England all the leaves have usually fallen by the end of November. In fact, in ordinary seasons, the elms (which shed their leaves late) are quite leafless by the middle of the month.

A. B. BASSET.

Fledborough Hall, Holyport, Berks, November 29.

Iridescent Clouds.

THERE was a fine example of clouds showing iridescence on December 4, from 8.50 to 9.5 a.m., in the south-eastern sky. It occurred on a large white cumulo-maculo cloud, the iridescence being confined to the upper and lower margins, which were much striated.

This was at first the same period *after sunrise* as I have commonly observed the phenomenon to occur *before sunset*, *i.e.* at about an hour's distance from each event (*vide* my letter on the subject, NATURE, vol. lviii., p. 390). I have not seen it before in the morning.

E. ARMITAGE.

Dadnor, Herefordshire, December 5.

The Origin of the Aurora Spectrum.

WITH reference to the question as to whether there is any auroral line in the position of the krypton line about 587, the nearest lines to this that have been observed in the aurora appear to be 5765 and 595 observed by Gyllenskiöld. His observations were only rough, but the question is whether they are near enough to the krypton line for either of them to be the same as it. If there is any auroral line about 556, it is likely that the great brilliancy of that at 557 would account for its not having been seen.

SVEN HEDIN'S "THROUGH ASIA."[1]

CAPTAIN FRANK YOUNGHUSBAND prefaced his charming work on Central Asia "In the Heart of a Continent," by a lament that his early education had been wasted on dead languages, so that he started on his travels ignorant of scientific methods of thought or observation (see NATURE, June 11, 1896). Dr. Sven Hedin has no such fault to find with his upbringing. Trained in physical geography in the University of Berlin under the great Asiatic traveller Baron von Richthofen, he chose the least-known parts of Asia as a field for exploration, and fitted himself as an explorer by years of preliminary study and Eastern travel. Few men, especially in this country, attracted instinctively to the studies which can make them geographers, have had the opportunity of becoming travellers, although many travellers have been stimulated by their experiences to take up the study of geography. Dr. Hedin writes, as he travelled, like an accomplished geographer. He was no sportsman; and, although a sedulous collector, he was neither botanist, zoologist nor geologist, possessing only that sympathetic general knowledge of natural science which is essential to a geographer, and invaluable to a traveller as a guide to observation. He not only qualified himself in practical astronomy and surveying, so as to collect trustworthy material for maps, but took special pains to master all necessary languages. Besides his native Swedish he was proficient in German, French, Russian and English, and could thus converse easily with every European traveller and official he met; he had already learned Turki, so that in western Central Asia he could question the natives directly, and in the course of the journey he acquired sufficient facility in the use of Mongol and Chinese to enable him to dispense with interpreters.

Being a translation, though a good one, "Through Asia" cannot be compared in style with the best English books of travel; but in substance it is so full, solid and interesting that this is soon forgotten. An awkward phrase, indeed, puzzles one occasionally, such as "diopters" (which may mean the sights for a plane-table); "temporal observations," instead of "observations for time"; and a few others. The word "glen" is very frequently used in a sense which appears to be the same as valley, but may contain some undesignated shade of difference.

King Oscar, whose interest in travel and in all matters Oriental is well known, interested himself in the proposed journey, and assisted in supplying the very modest funds (1900*l*.) required for what has turned out to be one of the cheapest, as well as one of the best, of the great journeys of the century.

Dr. Hedin travelled altogether 14,600 miles, of which 2020 had never before been traversed by a European. He made a continuous map of his route for 6520 miles, which is now being worked up in the great cartographical establishment of Perthes in Gotha, and innumerable observations on the volume of rivers, the depths of lakes and the temperature of air, water and soil, which will all be discussed and published separately. His collections of natural history specimens and archaeological remains will also be made the subject of monographs. Thus although the mass of the scientific data obtained is large, but little of it is considered in this book, which is a compressed narrative of the whole three years' journey, containing, indeed, a fair amount of adventure quietly told, and just enough of the more technical aspect of geography to enable the general reader to understand the explorer's motives and appreciate his results. Enough is stated, however, to show that it is the record of one of the finest scientific journeys ever carried out in trackless Asia.

[1] "Through Asia," by Sven Hedin. With nearly three hundred illustrations from sketches and photographs by the author. Two vols. Pp. xx + 1278. (London: Methuen and Co., 1898.)

Dr. Hedin's work was divided into several expeditions, between which he rested for a few months at a time at Kashgar and other Asiatic cities. The first journey, after driving across the Kirghiz steppe round the north of Lake Aral to Tashkent, was the crossing of the Pamirs in the winter of 1893 by a road traversed in the open season by the Russian garrison of Fort Pamir, and kept open for their mails all the year. The most interesting incident of this journey was the sounding of the great Kara Kul by means of holes cut in the ice. The lake is without outlet and salt, with an area approaching 150 square miles, and the elevation of its surface above sea-level is 13,000 feet; it is completely surrounded by lofty mountains. The lake is divided by a low peninsula into two basins; the eastern, in which three soundings were made, varied from 41 to 63 feet in depth, with a temperature of from $34^{\circ}\cdot2$ to $35^{\circ}\cdot2$ at the bottom, and the ice was from 3 feet to 3 feet 6 inches thick. The western basin was tested by four soundings, of which the shallowest was 256 feet with a bottom temperature of $35^{\circ}\cdot8$, and the deepest 756 feet with a bottom temperature of $38^{\circ}\cdot3$. The thickness of the ice here was only from 1 foot 4 inches to 1 foot 9 inches; and the temperature of the air was -20° F. at night. The depth, although considerable, should hardly, however, be called "abysmal," even for a lake.

The second piece of work undertaken was the study of the great snow-clad mountain Mustagh-ata, which is the loftiest summit of the Pamirs, towering to 25,600 feet. Dr. Hedin ascended its slopes to the height of 20,660 feet, where he passed the night. To this elevation he was able to ride on a yak, and bring up his whole camp equipment: so that a trained mountaineer to whom it is a pleasure to climb higher than other people, should here have a good opportunity for making a "record" climb from a comfortable base. Dr. Hedin, however, was not a mountaineer, and defeated in the attempt to climb, he made a careful study of the glaciers all round the mountain. The snow-field of Mustagh-ata measures roughly 10 miles by 6, and from the snow-line valleys radiate in all directions, many of them occupied by great glaciers, the streams from which are collected in rivers on the plain, which flow round the base of the mountain for three-quarters of its circumference before they turn finally to north and south. The work on Mustagh-ata occupied, with occasional intervals, the time from April to October 1894, and during much of this time Dr. Hedin lived amongst the Kirghiz as one of themselves, and obtained a great deal of information as to their customs and mode of life. The winter was spent in Kashgar, where Mr. and Mrs Littledale happened to be staying at the time, preparing for their great journey across Tibet from north to south.

In February 1895, Dr. Hedin set out on his most adventurous journey, in which he barely escaped with his life, in the desert of Takla-makan. Crossing the Yarkand-daria at 39° E., the desert was crossed in a more or less easterly direction. The party had eight camels, of which only one survived; and the guide with another man, who were believed to have treacherously taken a smaller supply of water than was ordered, perished of thirst in the sand, possibly through being unable to desert so soon as they had planned. Fifteen days were expected to suffice to reach the Khotan-daria, but twenty-six were required. During the greater part of this time the scenery was one monotonous waste of yellow sand dunes, the surface unvaried by a vestige of vegetation, or even by a stone. The largest dunes were as much as 200 feet in height with a crescentic ground plan, and exceedingly steep on the leeward slopes. It was impossible to follow a straight course, and as the intermediate low ground was often occupied by "pools" of the finest sand, in which the camels sunk deeply, it was often necessary to wind over the slopes, following the crests of successive dunes. No living thing was to be seen. When at last Hedin emerged from the sand, and struck the Khotan-daria, he was alone, on foot, and in rags. By carrying back a supply of water in his boots he saved one of his men; two others with one camel also escaped, and brought some of the instruments and all the note-books; so that what at one time appeared likely to be irretrievable disaster was averted, but narrowly, as he was a week without food. The river was followed northward to Aksu, and Kashgar re-entered on June 21. While waiting for the new instruments, which had been telegraphed for to Europe, Dr. Hedin took another run to the Pamirs, a sort of pleasure trip, for he had the good fortune to share in the festivities of the Anglo-Russian Boundary Commission.

In December 1895 he left Kashgar finally for further explorations in the desert, travelled to Khotan through Yarkand, and along the southern margin of the desert, and collected so much material that he proposes to make another book of it. The *kara-buran*, or black sandstorm, which is common in that region at certain seasons, seems to be similar to the American tornado. This type of storm occurs only in summer, and almost always in the afternoon, rarely lasts above an hour, comes more frequently from the west than from the east, and is so furious in its intensity as to sweep sheep away bodily. Another strip of the desert was crossed from the Khotan-daria to the Keriya-daria, a river never before visited by a European; and on the way Dr. Hedin discovered the ruins of an ancient city, called Takla-makan, built of wood, and full of relics of an ancient time, when the prevailing religion was Buddhism. The curious appearance of the ruins as they project from the sea of dunes is well brought out in the illustration on the next page. These dunes have a uniform angle of 33° with the horizon on the steep leeward slope, while the windward slope varies from 20° to as little as 1°; a calculation gave about 160 feet per annum as their average rate of advance. The grassy borders of the Keriya-daria were found inhabited by a race of shy shepherds, who rarely visit a town, and had never seen a European before. The desert margins abounded in wild camels, several of which were shot. From all Dr. Hedin could see and hear of them he was convinced that they are descendants of the tame camel, their present wild life being a reversion to nature, not a primitive state.

Proceeding northwards, the Tarim river was crossed on the ice in February; this river, in the latitude of Naples, is said to remain frozen for three months of the year, a good example of the effect of continental climate, although the atmosphere is too dry to furnish any snowfall.

The Lop-nor region was made the object of careful study, and geographically this is one of the most interesting parts of the whole book. A controversy as to the character of Lop-nor has been going on for many years. The great Russian explorer Przhevalsky explored a lake which he held to be the ancient Lop-nor; but it was fresh, yet without outlet, which proves that it must be of very recent formation. Richthofen pointed out that the ancient Lop-nor, placed by Chinese geographers a degree further north, must be salt if it still exists; but Hedin discovered that there is a very recent lake which he believes reoccupies the western part of the bed of the old Lop-nor, which has been nearly filled up by desert sand. The whole region is almost at the same level, and the lakes are so thickly overgrown with huge reeds, that it is very difficult to trace the boundaries of the shallow sheets of water, which evidently shift in position from time to time as the rivers of the desert also do. The Lop-men are very expert canoists; but the translation is obviously in error in speaking of them as "rowing" the long narrow canoes with "oars," which would be impossible without outriggers; the illustrations show them paddling by means of paddles, a very different method of propulsion.

The last piece of exploration recorded in the book has

redeemed a long strip of the map of Tibet along the parallel of 36° N. from absolute blankness. Leaving Khotan with a large caravan of horses, donkeys and camels in June 1896, Dr. Hedin proceeded eastward, skirting the desert to Kopa, then turning south-west into unknown country across the west end of the Altyn-tagh, he crossed the parallel range of the Arka-tagh (close to the place where Littledale crossed it going south), and marched eastward for twenty-six days along a great elevated region averaging nearly 16,000 feet in height, with the Arka-tagh bordering it to the north, and another snowy range, the Kokoshili, to the south. This is spoken of as a "latitudinal valley," or as a valley bordered by "latitudinal mountain ranges," but the sense of the term is not clear, the expression *longitudinal valley* would appear to be the correct one, as it seems to be a vast trough between parallel mountain ridges. The centre of the trough is occupied by a succession of small basins, each an independent centre of drainage, and each containing a long narrow salt lake lying east and west. It is really a land-surface in the making. If the precipitation had been heavy enough to fill these basins and start rivers flowing from one to another, the whole valley would now be drained by a great axial river; but in default of river erosion the basins remain untapped, and wind and frost alone are fashioning their peculiar topography. A little yellow grass was found in patches in the basins, on which vast herds of wild asses and wild yaks were feeding; but for fifty-five days no human being or human habitation was seen. We look forward with much interest to the detailed description of this interesting region, the map of which, prepared in Sweden, is obviously only provisional, and not accurate; for instance, the distance between camps xxii. and xxiii., said in the text to be the longest day's journey, is represented as very nearly the shortest, and the position assigned to the camps does not fit the description. At length, on October 1, 1896, Mongols were met, and a descent made from the Tibet plateau to the Tsaidam swamps, whence the route lay over known ground to Peking, and thence Dr. Hedin returned to Sweden across Mongolia, Siberia and Russia.

When one contemplates such a journey, so brightly and popularly told, full of adventure, hardships and solitude, yet every hour of it occupied in collecting, observing, note-taking and map-making, and when one remembers that only German training can make such work possible at present, even to the most adventurous and persevering traveller, it is impossible not to be struck from another side by Sir John Murray's feeling, expressed in his recent appeal for Antarctic exploration:—

FIG. 1.—The ruins of Takla-makan east of the Keriya-daria.

"The conviction that we are, in exploration and scientific research, not doing anything like our best, is much deepened when we compare our present efforts with what is being done in these directions by other progressive nations." HUGH ROBERT MILL.

THE AMERICAN AGRICULTURAL YEAR-BOOK.[1]

YEAR by year the official volume issued by the Department of Agriculture at Washington appears to increase in interest and importance, and the latest addition to the series is well-nigh bewildering in the

[1] "Year-book of the United States Department of Agriculture, 1897." Pp. 492; with 40 plain or coloured plates, and 45 figures in the text. (Washington: Government Printing Office, 1898.)

scope and variety of its contents. Making every allowance for the fact that the functions of the United States Minister of Agriculture extend over an area practically as large as that of Europe, and for the circumstance that much of the agricultural practice of the western hemisphere is still in the tentative stage, the volume is nevertheless impressive on account of its encyclopaedic character. Precedence is given to the annual report of the Secretary, who is the political head of the Department, his position being comparable with that of the President of the Board of Agriculture in Great Britain. This document, of which a preliminary issue was made at the close of last year, occupies 50 pages, and deals comprehensively with the whole work of the Department. A section of 220 pages is next taken up by articles, nineteen in number, written by the heads of the several divisions of the Department, and setting forth the relation of the work of each division to the farming industry. This, we may remark, is a special feature of the current volume, and is the outcome of an express wish on the part of the Secretary, who took over the reins of office for the first time last year. The third section, extending to 340 pages, is one with which readers of the Year-book are familiar, as it has been a feature of previous volumes.

FIG. 1.

It consists, on this occasion, of a series of papers by acknowledged authorities on such subjects as the fruit ndustry, birds that injure grain, lawns and lawn-making, utilisation of hybrids in plant-breeding, soil problems, seed testing, leguminous forage crops, danger of importing insect pests, and the utilisation of by-products of the dairy. An appendix of 140 pages is well filled with a variety of useful matter, mainly statistical; but we do not observe at p. 714, where the area under wheat in 1897 is given as 39,465,066 acres, any reference to the fact that this represents a deviation of nearly 5,000,000 acres form the true extent of surface thus occupied, the under-estimate being apparently the result of an accumulation of errors for a series of years. Lastly, the volume is furnished with an admirable index of 32 pages, which adds greatly to its value as a work of reference.

A few examples, selected at hazard from different parts of the year-book, will serve to indicate the nature and value of the information which it conveys. Attention has been bestowed upon the investigation of certain crops, the produce of which is largely imported, but which could probably be grown with profit in the United States. Chicory is a case in point; the whole of this material required for consumption has hitherto been imported, but it is believed that in the course of ten years the country will be growing enough to entirely meet the hom[e] demand. Ten years ago the United States importe[d] annually about 130,000 dollars' worth of insect powde[r], but the experimental cultivation of pyrethrum in Cal[i]fornia proved a success, the result being that the impo[rt] trade referred to has dwindled away. The loss in th[e] United States from the diseases affecting cereal crops [is] estimated to amount to 25,000,000 dollars or 30,000,00[0] dollars annually. Cotton, tobacco, potatoes and oth[er] staple crops are correspondingly damaged. In one yea[r] the loss arising from diseases of orange, lemon and othe[r] citrus fruits was estimated at more than 450,000 dolla[rs] in Florida alone. From plant-diseases of all kinds th[e] loss to the entire country is put at 150,000,000 dollars t[o] 200,000,000 dollars annually. Against such calamitie[s] the work in the division of vegetable pathology is makin[g] steady progress, and significant examples are given o[f] the benefit that has thus already accrued to the grape grower, the nurseryman and the orchardist. Th[e] diversification of crops is advocated as a check upo[n] "the marked geographic concentration of agricultura[l] productions," which has resulted in twenty-five States, o[r] just half the total number, producing 98 per cent. of th[e] cotton, 95 per cent. of the maize, 95 per cent. of th[e] barley, 93 per cent. of the oats, an[d] from 80 to 90 per cent. of the wheat[,] rye, buckwheat, tobacco, potatoes an[d] hay grown in the entire countr[y]. Soils are being studied with a thoroughness that is probably unparalleled. The classification of soils o[n] a geological basis, their texture, thei[r] structure, and their relation to water are receiving the fullest attentio[n]. With regard to the cause of the movement of water in soils, "it was understood that it was the contractile powe[r] of the film of water around the soi[l] grains that caused the movement o[f] water to the plant. It appears now from a minute study of this problem that the movement is dependent upon the curvature of this film rather than upon the total area of its surface." Many an English traveller on the western prairies has been struck by the seemingly harsh and innutritious herbage upon which cattle and horses nevertheless live and thrive. A discussion of the value as forage of so-called weeds permits a reference to various plants which are drought-resisting, or thrive on alkali lands, and are valuable as forage. They include white sage (*Artemisia* spp.), green sage (*Bigelovia* spp.), sweet sage or winter fat (*Eurotia lanata*), salt sage (*Atriplex* spp.), and grease wood (*Sarcobatus vermiculatus*). It is probable that these could be profitably grown under cultivation, and thus made to yield a much larger amount of forage than is now obtained. The contention that every farm is an experiment station cannot be controverted, and it would be advantageous to farmers in all countries were they more habituated to the regular use of the note-book. The cultivation of catch crops to maintain a supply of nitrogen in the soil, is a headline that cannot fail to attract the eye of English agriculturists. If catch-cropping is understood and intelligently practised anywhere, it is on the light arable lands of England, where the system may almost be said to have originated —at a time, moreover, when practice was in advance of science, for farmers had approved and adopted the system before the extension of our knowledge of the nitrogen problem had supplied the theoretical justification. The work of the chemical division with regard to the development of cane and beet, and other sugar-producing crops,

has been fruitful in result. In the course of experimental work occupying eight years, the percentage of sugar in field crops of sorghum was raised from 9 to 14. The investigations concerned with beet cultivation have been so successful that the establishment of an indigenous sugar industry is now certain, and the benefit to American agriculture in the near future will be measured by hundreds of millions of dollars.

It would be instructive to refer to the work of the Weather Bureau, and of the divisions of entomology, agrostology and forestry; but it must suffice to conclude with a few observations on the bureau of animal industry.

Those who have been engaged in recent years in the administration of the Diseases of Animals Acts in Great Britain will best appreciate the comprehensiveness and the excellence of the work of the Washington Bureau. It is a bold statement to make, perhaps, that the whole of the United States territory—from the Atlantic to the Pacific, and from the great lakes to the Gulf of Mexico—has been swept free from pleuro-pneumonia; and those who are familiar with the history of this most troublesome disease in Great Britain will only hope that the assertion may prove to be true.

The microscopic inspection of pork intended for export is worthy of all praise, and we reproduce an illustration showing this work in progress. Last year 1,881,309 specimens were thus examined for trichinae, and only 13,325 were found infested; the cost of this inspection was 111,670 dollars.

EDWIN DUNKIN, F.R.S.

At the ripe age of seventy-seven, with the consciousness of having fulfilled a useful career, and amid the respect and sympathy of his associates, Mr. Edwin Dunkin has passed away, again diminishing the small band of zealous assistants, that Sir George Airy collected around himself, when some sixty years ago he undertook the reorganisation of the Royal Observatory, and inaugurated that system of uniform and continual observation which has ever since remained the chief characteristic of that institution. To trace the career of Mr. Edwin Dunkin is to recall the history of the Observatory under its late director, for during nearly half a century Mr. Dunkin took a prominent part in its activity, filling many responsible positions, till finally he became the chief and confidential assistant. In whatever capacity he was placed he was admirably adapted to it by reason of his painstaking and accurate observation, his loyalty to his chief, and his keen interest in the science. It was his fortune to see and to assist in the creation and development of a magnetical and meteorological department, to witness the establishment of a system of extra meridional observations of the moon, to see the observations of Right Ascension and Zenith Distance effected by a single instrument, and to mark the substitution of chronographic registrations for the older method of recording transits. He remained at his post long enough to note the introduction of the spectroscope and of photographic processes: in a word, to form a link between the methods of the old astronomy of position and the purposes of the newer physical science. He lived to see the staff of the Observatory trebled and quadrupled, as fresh objects of inquiry were brought within its scope; and that he could adapt himself to every change, and lend his experience to ensure the smooth working of the ever-growing machinery, is to say that he was an able and useful official, rendering good work in his day and generation.

Naturally, from his official position, Mr. Dunkin took part in many of the scientific expeditions organised at the Royal Observatory under Government auspices. Among the earliest of these was a visit to Christiania to observe the total eclipse of the sun in 1852. The instrumental equipment provided, consisted of a telescope of $3\frac{1}{2}$ inches aperture, mounted on a firm tripod, and provided with steadying rods. If this optical assistance appears to us now antiquated and inadequate, the observations made with it read even more strangely. We may quote one sentence from the official report, which illustrates the progress of physical inquiry accomplished within a single scientific life. Mr. Dunkin is describing his first impressions of a solar prominence:

"My eye was intently fixed upon it for about a minute of time, and during that interval not the slightest change took place in its form. Its colour was pink, or rose colour, but the shade was not very deep. It seemed to me at the time, from the excessive steadiness of this prominence, and from the fact that I had zealously watched it for so long an interval without its undergoing any change, that this object had some connection with the *moon*. However . . . it is possible I may be deceived."

Another classical experiment in which he was engaged, and to whose minute care the measure of success obtained was mainly due, had reference to the determination of gravity at different distances below the earth's surface, by means of pendulum experiments. Some thirty years previously, the late Astronomer Royal had carried out an investigation of the same nature, which had not led to a satisfactory termination; but in the case of the Harton Colliery, where experiments could be effectively made at a depth of 1260 feet, Sir George Airy expressed himself as quite satisfied with the result achieved, and considered that it established a favourable precedent for similar inquiries in the future. The result was to show an increase in the force of gravity of 1/19000 at the depth reached. Longitude determinations may be said to come almost within the daily routine of the Royal Observatory, and it would not be necessary to refer to the share Mr. Dunkin took in these, but for the fact that the system of telegraphic signals was a new and practically an untried method when Mr. Dunkin and M. Faye were engaged in the longitude determination of Paris. Doubtless there were difficulties in those days, which have been so effectually overcome that they have been forgotten; but as a pioneer, Mr. Dunkin, and those who were associated with him, must have exhibited a manipulative skill which we may now fail to appreciate.

We should do less than justice to Mr. Dunkin's memory if we did not recall his long and eminent services to the Royal Astronomical Society, which he served in various capacities. He was Secretary at the time of the removal of the Society's property from Somerset House to its present quarters, and the reorganisation of the library, and the restoration of order into the Society's affairs, which had fallen a little out of gear, devolved mainly upon him, but his methodical habits and unstinted devotion to the interests of the Society ensured complete success in the regularity and management. Among other services to the Society, one may mention the many obituary notices which it was his misfortune to have to write, but which were always recognised as just and appreciative, and not without literary merit. His scientific communications had generally some reference to points of importance in practical astronomy, such as the treatment of personal equation in observations, or the determination of proper motions of stars. He was eminently a practical astronomer, rendering useful, if less brilliant work than the mathematician; but the many solitary hours he passed at the eye-piece of the transit circle, or the altazimuth, will not be without their due effect in advancing the interests of astronomical science.

W. E. P.

NOTES.

WE are informed that the Government is prepared to make the financial arrangements necessary to enable the Imperial Institute to become the headquarters of the Organisation of the New University of London. This decision of the Government was brought before the Senate at its meeting yesterday by the Vice-Chancellor, and it is hoped that no unnecessary delay will occur in securing the agreement of all parties concerned. While it is doubtful whether a Faculty of Commerce commensurate with the other Faculties can be at once established, it is most important that the various subjects which would naturally be included in it should be taught. This teaching might fairly find a place in the Imperial Institute under the authority and control of the New University. Some of the instruction would be germane to the valuable collections of raw materials, &c., in the Institute.

A VERY considerable discussion of an informal character is now going on among many interested in the various institutions which may form part of the new University. It is to be deplored that there is a great probability of the work of the Commission being hampered by the fact that many of the suggestions now being made are more inspired by the local interests concerned than by the desire to help on the educational question in the abstract. We use the word abstract in no pedantic sense, and with a full appreciation of the concrete questions involved. The Commission has to deal with an area defined by a radius of thirty miles, a population which we may roughly estimate at seven millions, and a large number of existing institutions. The amount of good the Commission will ultimately produce along new lines will, we take it, be capable of measurement by the success it will achieve in coordinating the old forces which are already at work, by working on the principle of organic growth and regarding what exists from the most general standpoint. It is from this point of view that we deprecate some of the suggestions now being made, because, if accepted, they will harm existing institutions, because the new University must not commence by localising itself, however high any local bid may be, and because again no good work will be achieved if any new suggestions be accepted before the actual condition is fairly grappled with, mastered and legislated for.

THE President and Council of the Geological Society will be "at home" to the Fellows on Friday, December 16.

THE *Pioneer Mail* states that the Nizam's Government has sanctioned the immediate construction of a complete and thoroughly equipped Pasteur Institute for Hyderabad. It will adjoin the hospital and medical school, and will be available in about six months for patients.

IN the forthcoming session of Congress, the Hurley Bill, providing for the adoption of the metric system of weights and measures in the United States and its compulsory use in all Government transactions except the completion of surveys of the public lands, will be again brought up. The Bill was defeated by only three votes in the fifty-fourth Congress, and the increased interest since given to the subject will, it is hoped, lead to the adoption of the measure.

A FEW particulars with reference to the discovery of a new system of incandescent electric light, by Prof. Nernst, of Göttingen, are given in *Science*. The light requires neither vacuum nor tender filaments. The essential point of the invention is that when magnesia is heated above 3000° C (a temperature far above the melting point of platinum), it becomes a good conductor, and a very weak current is sufficient to keep it in an intensely luminous condition. Either direct or alternating currents may be employed, and the magnesia is little injured by use. The preliminary heating Prof. Nernst accomplishes by placing the magnesia in the focus of a reflector. On the inner side of the reflector is a spiral wire of platinum, which when brought to incandescence by a current, produces heat sufficient to render the magnesia a conductor; a current is then passed directly through the oxide by the wire, and that in the spiral is shut off. As advantages over the ordinary incandescent lamps Prof. Nernst claims that the same amount of light can be furnished at one-third the cost, and as the magnesia allows of being heated to a much higher degree than a carbon filament a purer light is obtained. The successful employment of a cheaper substitute for the platinum is also announced, though the name is not made public.

PROF. GEORGE FORBES, F.R.S., referred to the utilisation of the Nile cataracts, in his recent lecture at the Society of Arts on long distance transmission of electric power. He remarked as follows:—"My report on this subject is in the hands of the Egyptian Government, and is their property; but I am not divulging secrets when I tell you that the electric lighting of Cairo could be done cheaper by power generated at the First Cataract than by steam engines at Cairo. The distance is 400 miles as the crow flies. Do not imagine that I propose lighting Cairo immediately in this way. The Government has far more important uses for the power, not only in the irrigation of the country as it is, but still more for the perennial irrigation which will be so much extended when the great reservoir designed by Mr. Willcocks, Sir William Garstin, and Sir Benjamin Baker shall be completed by Mr. John Aird. You may take it as certain that before long the cataracts will be harnessed and forced to assist in developing not only Egypt proper but the Sudan, and especially the Dongola province up to the Fourth Cataract, which, with efficient irrigation, may become the most fertile country in the world."

AFTER several visits to the Orkneys, Prof. Newton succeeded this summer in landing upon the Holm of Papa Westray, a small island lying to the eastward of the larger one, from which it is separated by a comparatively narrow and shallow sound. A survey of Papa Westray in 1888 led Mr. Buckley to believe that he had found the last breeding place—reputed to be thereon—of the Great Auk or Garefowl (*Alca impennis*). The unsuitableness of any part of the island as a breeding place for such a bird was afterwards pointed out; but an examination of the Holm of Papa Westray led to the discovery of a locality adapted in every way to the habits of the Garefowl, and Prof. Newton considers that there is no room for doubt that the Holm was the true home of the species whose extirpation, so far as Orkney is concerned, was compassed in 1813. In connection with this subject it is interesting to mention that Mr. Symington Grieve contributes to the *Transactions* of the Edinburgh Field Naturalists' and Microscopical Society some additional notes on the Garefowl, with special reference to two newly-recorded skins. He states that the existing remains may now be summarised as follows:—Skins, 80-82; skeletons, more or less complete, 23-24; detached bones, 862-874; physiological preparations, 2-3; eggs, 71-72.

THE weather reports issued by the Meteorological Office show that during the month of November the rainfall in different localities has been considerably influenced by the tracks of the storms, some of which have passed to the north and others to the south. Generally speaking, the rainfall has been excessive in the north-west and south-west of our islands, and deficient in the eastern parts. But not unfrequently stations not very far apart have received very different amounts of rainfall. At

Stornoway (Hebrides) the fall was about double the average, the excess being 5 inches; while at Sumburgh Head (Shetlands) there was a deficiency of 0·27 inch. At North Shields there was an excess of 0·95 inch above the mean for the month, while at Leith there was a small deficiency. The following values above or below the monthly mean are noteworthy:—Valencia, + 1·26 inch; Roches Point, − 0·96 inch; Hurst Castle, + 1·25 inch; Dungeness, − 1·83 inch; Holyhead, + 0·08 inch; and Liverpool, − 1·12 inch. Generally speaking, the rainfall since the beginning of the year is still considerably deficient, except in the north of Scotland, where the excess is above 9 inches.

AT the meeting of the French Meteorological Society on November 3, under the presidency of M. Poincaré, M. Teisserenc de Bort presented the first part of a very important work by Dr. Hildebrandsson and himself, entitled "Les bases de la météorologie dynamique. Historique, état de nos connaissances." This part contains the history of all the ancient researches from the time of Aristotle to the present date. In the second part, now in the press, the history will be continued, and will be followed by theoretical questions, such as the distribution of aqueous vapour in the atmosphere, and that of the meteorological elements over the surface of the globe. A paper by M. Coeur de Vache was read on the atmospheric electricity of the months of March 1886–1895, or during a period of 213 days. This investigation shows that the diurnal oscillation of atmospheric electricity depends especially upon the humidity of the air, both with regard to its amplitude and to the normal hourly values. The other papers read related to the unmanned balloon ascents of October 3 last, by M. Teisserenc de Bort, and to the action of the moon on the movements of the atmosphere, by M. Poincaré.

WE have received a copy of "Observations and Researches" made at the Hong Kong Observatory during the year 1897, under the superintendence of Dr. W. Doberck, the director. In addition to the usual observations and results of the meteorological and magnetic instruments, the report contains detailed information upon the other valuable work carried on at the observatory. For the daily weather forecasts a complete success of 65 per cent., and a partial success of 31 per cent., are claimed. Following the method used in some other meteorological establishments, and adding together the sum of total and partial success, the high figure of 96 per cent. is obtained. During the year 1897, besides the meteorological registers kept at forty stations on shore, the log-books of 283 vessels have been copied, for use in the construction of trustworthy pilot charts of the Eastern seas. The report also contains the third edition of the law of storms in the Far East, to which we briefly alluded in our issue of October 20. Dr. Doberck is very sanguine about the results of this investigation, and states that the typhoons, about which little was known when the observatory was built, in 1883, are now among the best understood atmospheric disturbances. A chart is given showing the average tracks of these storms.

THE question of the porosity of thin steel plates under heavy hydraulic pressure having been raised (says *Engineering*), experiments have been carried out at the Washington Navy Yard with the view of settling the point in a practical way. Pieces of sheet steel of ¼ inch, ⅛ inch, $\frac{1}{16}$ inch, and $\frac{1}{32}$ inch in thickness were subjected to a water pressure of 6000 lb. per square inch, and in no case was any percolation found. A ⅝ inch rivet joining two ⅛-inch plates also proved tight under the same pressure. A test was also made to determine the friction of water under high pressure, and, while it was inconclusive, there was no evidence that the friction of water under high pressure was any greater than the friction of water not under pressure.

AMONG the methods of reducing a compressed gas to a lower pressure by irreversible transformations, those of Joule's well-known experiment of expansion into a vacuum, and Lord Kelvin's experiment of expansion through a porous plug are the most important, and the recent applications of the Kelvin effect to the liquefaction of gases has added fresh interest to the latter. An investigation of the thermodynamics of the process in question is given by M. A. Witkowski in the *Bulletin* of the Cracow Academy, pp. 282–295. These observations support the view that beyond certain limits of temperature and pressure, expansion of a gas is accompanied by heating instead of cooling, and the author investigates the temperature of reversal for air and for hydrogen. The conclusions tend to show that in liquefying gases by expansion there is no advantage in making the initial pressure too great; a pressure of 200 atmospheres, as employed in Linde's machine, being amply sufficient. The cooling resulting from expansion into a vacuum is rather greater than would be obtained for the same pressures in the Kelvin-Joule apparatus.

THE study of hydrodynamics has been greatly facilitated by the series of reports which have been from time to time brought out dealing with the progress made in the subject during various periods. These include Sir G. G. Stokes' report to the British Association of 1846, Prof. Hicks' reports of 1881–82, Mr. Love's paper on Vortex Motion in the *Mathematische Annalen* for 1887, Prof. Hicks' account of the same subject in his sectional address to the British Association at Ipswich in 1895, and Prof. Darwin's Encyclopaedia article of 1888, on Tides. In *Science* for November 11, Prof. Ernest W. Brown, F.R.S., gives an interesting account of recent progress towards the solution of problems in hydrodynamics which have not been included in these previous reports. The author deals at considerable length with wave motion, viscosity, and two-dimensional discontinuous motion, pointing out that no case or three-dimensional discontinuous motion has been solved. In connection with viscosity Prof. Brown remarks that "in all problems hitherto solved, only the first powers of the velocities are taken into consideration." But a paper was published by Mr. Whitehead, in the *Quarterly Journal of Mathematics* (vol. xxiii. p. 78), dealing with second approximations to viscous motion, notably for the fluid surrounding a rotating sphere; and the conclusions arrived at seem rather to cast doubts on the validity of the ordinary first approximations. As Mr. Whitehead's paper seems little known, the present reference may save some mathematician the trouble of solving the same problem (as did the writer of the present note), and then finding that he has been anticipated.

A RECENT number of the *Revue Scientifique* contains the continuation of an article by M. P. L. Simond on the transmission of plague-virus. It is now well recognised that rats not only herald the advent of plague, but are themselves largely responsible as direct disseminators of the morbific material; but, as M. Simond points out, they do not account for all the subtle means by which the virus finds its way to the human subject. Further careful researches now show that parasites in the shape of fleas are extremely dangerous disseminators of plague-bacilli. Suspicion fell on these vermin, inasmuch as it is far easier to infect an animal with plague by subcutaneous inoculation than it is through the alimentary canal. A large number of experiments have been carried out by M. Simond to test the validity of his hypothesis, and just as Yersin showed that flies could transmit virulent plague-bacilli, so Simond has found that fleas taken from plague-stricken rats can communicate the disease to healthy animals, vermin from such sources containing in their excreta the virulent plague microbes. We have long known that dirt and plague go hand in hand, and M. Simond's instructive researches furnish yet another proof of the cardinal

importance of combating the disease by unremitting attention to sanitary conditions.

Mr. C. S. Stanford Webster calls attention, in the *Chemical News*, to a novel production of vortex motion. He states that when the freshly gathered leaves of the native Eucalyptus tree (*Eucalyptus globulus*) are ignited, they project vortex rings in considerable numbers in succession, accompanied by a spluttering noise. The best results are obtained by holding the scythe-shaped leaf vertically and igniting the apex—this being the part where the greatest number of translations are obtained. Mr. Webster thinks that possibly in the production of these vortex rings, blisters are first formed by the extrusion of the cuticular tissues, and, on the blisters bursting, air or aqueous vapour is spontaneously liberated, the rings being rendered visible on their contact with the smoke from the burning external portion of the leaf. The leaves of the small English variety of Eucalyptus possess similar properties to the native product, but in a lesser degree, the rings projected being insignificant in size, comparatively speaking.

We have received a letter from Mr. Charles W. Purnell, of Canterbury, New Zealand, criticising two of the statements made by Prof. Lloyd Morgan in his notice of Prof. Thorndike's experimental study of animal intelligence (Nature, July 14). Prof. Purnell sees no reason for denying to animals either "conscious [*i.e.* volitional or purposive] imitation," or "memory as involving true localisation in time and space." The facts adduced by Mr. Purnell, however, are not likely to be denied by Prof. Lloyd Morgan or by any careful observer of animal behaviour. The questions he raises seem entirely to turn on the definition of terms, for a discussion of which we cannot afford space.

The anthropological part of the *Journal* of the Asiatic Society of Bengal (vol. lxvii.) contains six papers, all of value. The taboo of names amongst the Santals is examined most carefully by Mr. P. O. Bodding, and his explanation of it seems convincing. Taking it in conjunction with other taboos, it seems to be a series of rules for defining and keeping intact the standard of conduct among the members of the tribal family, and it is well to note the scarcely veiled system of polyandry which obtains with regard to the wife of the family chief and his brothers. If this is the survival of an older social stratum, while the taboo existing between the family chief and the wives of his younger brothers marks the rise of a newer order of things, it seems that we have here a most interesting phase of social evolution. The Santals are divided into twelve totemistic septs, and Mr. Bodding also examines the taboos connected with this cult; and in another paper the same author deals with the salutations used by the Santals in a manner to show their bearing upon tribal society. The rain ceremony from the district of Murshidabad, Bengal, by Mr. C. C. Mitra, is highly instructive, especially as the author shows its close connection with Lithuanian and other European customs of modern times. By the same author is a paper on the lizard in Indian superstition and folk-lore. Mr. E. A. Gait's paper on human sacrifice in ancient Assam is a useful description of this practice according to the tribes among whom it obtains.

The *Bulletin* (vol. ii. No. 2) of the Madras Government Museum, by Mr. Edgar Thurston, shows how useful has been the work begun by Mr. Risley. The physical measurement and other particulars of the Eurasians of Madras and Malabar, accompanied by excellent photographs, are taken from a sufficient number of persons to be sure that normal results have been obtained, and there is an additional note on tattooing, with illustrations.

Mr. Henry Frowde, Oxford University Press, announces the forthcoming publication of a monograph on "The Micro-organism of Faulty Rum," by Prof. V. H. Veley, F.R.S., and Lilian J. Veley (*née* Gould). This micro-organism, which is said to have caused damage to the extent of many thousands of pounds, has only recently been isolated.

Prof. Wilhelm Wundt's "Grundriss der Psychologie" (Leipzig: Engelmann. London: Williams and Norgate) has reached a third edition. The original work, noticed in Nature, vol. liii. p. 604, 1896, has been revised and slightly enlarged. —Mr. Engelmann has also just published a second enlarged edition of Prof. Karl Eckstein's "Repetitorium der Zoologie." The work has been completely revised, and many additions have been made in the various sections.

A second edition of the late Carl Reutti's "Übersicht der Lepidopteren-Fauna des Grossherzogtums Baden" has been published by the Gebrüder Borntraeger, Berlin. The new edition has been prepared by Dr. A. Spuler, who was commissioned by the Karlsruhe Naturwissenschaftlich Verein and Herr Adolf Meess to undertake the work.—MM. Gauthier-Villars, Paris, have published a second edition of M. de Fonvielle's "Ballons-Sondes," a little volume containing an account of the methods and results of experiments with free balloons sent up with recording meteorological instruments.

The different methods of recording the movements of seismographs form the subject of a brief, but useful, paper by Dr. Cancani in the last number of the *Bollettino* of the Italian Seismological Society (vol. iv. p. 73). Omitting the photographic method on account of its expense and neglect of details, there remain two others, in one of which the record is traced in ink flowing from counterpoised pens, and in the second on smoked paper by means of very fine threads of glass. Dr. Cancani has recently employed both methods at the Rocca di Papa Observatory, and decides without hesitation in favour of the latter, the diagrams being clearer and the friction of the pointers very much less.

Two remarkably cheap and good globes—one celestial and one terrestrial—published by Messrs. George Philip and Son, have been sent to us for notice. Each globe is 6 inches in diameter, and is mounted in a solid brass semi-meridian on a polished stand. The celestial globe has upon it all stars down to the fifth magnitude, printed in white upon a dark blue ground; and also some nebulae and star-clusters. The stars are considered to be viewed from a point outside the globe, and not, as is the case with celestial globes usually, from the inside. The globe may thus be regarded as a collection of star-maps mounted for convenience upon a sphere. The terrestrial globe is very clearly printed; it shows ocean currents, steamer routes, and other matters of geographical importance. Both globes will be of assistance to teachers of geography, but their educational value would have been increased had it been possible to include a horizon with each of them.

Messrs. Griffin and Sons, Ltd., wish attention drawn to the fact that they have recently removed from their old premises in Garrick Street, Covent Garden, to 20-26, Sardinia Street, Lincoln's Inn Fields, London, W.C., where buildings have been specially constructed for their work. The same firm has just published the eighth edition of their catalogue of electrical apparatus, a copy of which has been sent to us. Among the scientific instruments and appliances included in the list are several noteworthy things. It is pointed out that Wimshurst machines with ebonite plates have many advantages over the glass plate machines, not the least being that they are not so liable to breakages. In the section of the catalogue containing

apparatus for experiments in voltaic electricity we notice a useful school galvanometer, having several novel features, and constructed in such a way that it can be entirely dismounted so as to explain the method of construction before the students in a class. Great care appears to be taken in the manufacture of resistance coils, all of them being tested and adjusted to within one-hundredth per cent. or one per cent. (according to price) of their value. In the magnetic section an interesting instrument described is Lenard's bismuth spiral for measurements of magnetic fields. The principle upon which the instrument is based is the change of resistance that occurs in bismuth when in a magnetic field; the alteration of resistance affording a means of determining the number of lines of force in the field tested. Many other instruments mentioned in the list show that Messrs. Griffin keep in touch with recent advances and educational requirements.

The *Electrical Review* for November 25 contains an interesting account, with illustrations, of the electrolytic chlorate works at St. Michel in Savoy. Power is supplied by the river Arc, sixteen turbines, each keyed to a dynamo, being employed. The solution of potassium chloride is placed in insulated vats lined with lead, and having a capacity of 11,000 gallons. The anodes are of platinum-iridium, and the kathodes of iron-nickel alloy. The primary electrolytic action is, of course, the resolution of the potassium chloride into potassium and chlorine; the potassium, however, forms potassium hydrate, and liberates hydrogen at the kathode. The potassium hydrate so formed is now brought under the influence of the chlorine liberated at the anode; and as a sufficient current density is employed to keep the temperature above 45°, the action proceeds according to the equation $6KOH + 3Cl_2 = KClO_3 + 5KCl + 3H_2O$. The chlorate is easily separated from the more soluble chloride by crystallisation. The works at St. Michel, and another at Vallorbes, are said to produce together 1800 tons of chlorate per annum. The introduction of the electrolytic process has resulted in a considerable fall in the price of chlorates.

The additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, presented by Mr. A. D. Michael; a Mantell's Apteryx (*Apteryx mantelli*) from New Zealand, presented by Sir Walter Buller, K.C.M.G., F.R.S.; two Dwarf Chameleons (*Chamaeleon pumilus*) from South Africa, presented respectively by Mrs. Todd and Mrs. C. Faraday Maypee; a Black Ape (*Cynopithecus niger*) from the Celebes, an Osprey *Pandion haliaetus*) captured at sea, a Praslin Parrot (*Coracopsis barklyi*) from Praslin Island, a Bell's Cinixys (*Cinixys belliana*) from Tropical Africa; a Home's Cinixys (*Cinixys homeana*) from West Africa, three Painted Terrapins (*Chrysemys picta*), a Salt-water Terrapin (*Malacoclemmys terrapin*) frnm North America, three Reeve's Terrapins (*Damonia reevesi*), a Black-headed Terrapin (*Damonia reevesi unicolor*) from China, four Caspian Terrapins (*Clemmys caspica*) from Western Asia, a Japanese Terrapin (*Clemmys japonica*) from Japan, four European Pond-Tortoises (*Emys orbicularis*), European, a Ceylonese Terrapin (*Nicoria trijuga*) from India, two Blackish Sternotheres (*Sternothaerus derbianus*) from Madagascar, a Spix's Platemys (*Platemys spixi*) from Brazil, a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, two Rufescent Snakes (*Leptodira hotamboeia*) from South Africa, deposited.

OUR ASTRONOMICAL COLUMN.

The New Comet Chase.—This comet seems to be brightening, and is now in a good position for observation. It is moving slowly towards the north-west, being situated now in the southern part of the constellation of Leo Minor, roughly in a prolongation of the line joining η and γ Leonis. The Centralstelle sends us a circular (No. 15), which informs us of the elements and a brief ephemeris computed by Coddington from observations made on November 23, 24 and 25. Another circular (No. 16), which has just come to hand, informs us of more accurate elements and ephemeris which have been computed by Herr. J. Müller from two Harvard photographs taken on November 14, and two Lick observations made on November 23 and 25. These are as follows:—

T = 1898 September 8·192 Berlin M.T.

$$\left.\begin{aligned} \omega &= 358^\circ\ 43'\cdot83 \\ \Omega &= 93\ \ 49\cdot05 \\ i &= 21\ \ 35\cdot35 \end{aligned}\right\}\ 1898\cdot0$$

$$\log q = 0\cdot33144$$

Ephemeris, Berlin Midnight.

The Nebula of Andromeda.—The variation in brightness of a portion of the nebula of Andromeda, as announced by Seraphimoff some weeks ago, does not seem to have been generally corroborated, and the observations of Prof. Barnard (*Astrophysical Journal* for November) do not suggest any variation. In June and July of the present year this observer made a series of measures of the nucleus with reference to two eleventh magnitude stars, one preceding and the other south, and during this time the nucleus was well seen, though not stellar. No trace of the Nova of 1885, although carefully looked for, could be observed. After Seraphimoff's announcement both the 40-inch and the 12-inch telescopes were turned on to the nebula, but "it was evident that no perceptible change had occurred in the nucleus or the nebula itself . . . and the impression has always been that the nebula is unchanged."

Not only this observer, but both Hartwig at Bamberg and Comas Sola at Catala (*Astr. Nach.* No. 3529), record no variation; the former from eye observations and the lattet from photographs taken before and after the announcement mentioned above.

The Planet Witt DQ.—In a previous number of Nature (November 3) we brought together much of the information that had been published concerning the interesting new planet discovered by Witt. The importance of this small planet, which at times approaches the sun nearer than Mars, necessitates that it should be closely watched, and its motion accurately determined. Needless to say, such observations are being carried out in many observatories, so that when a sufficiently large part of the orbit has been described we shall be presented with more accurate elements. The elements previously published by Berberich show now deviations from the true ones as gathered from the observed and calculated positions of the planet. Mr. H. N. Russell, of Princeton (the *Astronomical Journal*, Nos. 448–450), has formed some new normal places from a comparison of several observations, and the elements he has deduced differ somewhat from those previously published. Millosevich, in an interesting contribution to the *Rendiconti della R. Accademia dei Lincei* (vol. vii., series 5A), has also computed some new elements, so we give the following comparison:

	Berberich.	Russell.	Millosevich.
Epoch.	1898 Aug. 31·5. M.T. Berlin.	id.	id.
M	220° 14′ 3″·7	224° 33′ 12″·3	222° 23′ 28″·7
ω	178 28 26·2 (1898·0)	175 47 50·1 (1898·0)	170 1 20·8 (1898·0)
Ω	0 3 48 53·0 (1898·0)	303 20 20·3 (1898·0)	303 24 53·1 (1898·0)
i	311 6 57·1 (1898·0)	10 45 1·8 (1898·0)	10 45 18·1 (1898·0)
ϕ	13 13 3·8	12 55 13·6	12 49 5·4
μ	2010″·131	2003″·86	2015″·119
log a	0·164521	0·1654245	0·163804
Period	645 days.	646·75 days.	644·06 days.

Prof. Simon Newcomb, in the same number of the *Astronomical Journal*, refers to the future oppositions of this planet

for the determination of solar parallax. The next most favourable opposition will occur in 1900 in November and December, so he gives a rough ephemeris for this period of approach. As this table will probably be useful for reference, we reproduce it below:—

	α	δ	Δ
	h. m.		
1900 Nov. 15	1 56	+ 54·7	0·358
20	45	54·0	·346
25	38	52·7	·336
30	32	51·5	·328
Dec. 5	30	49·7	·322
10	32	48·2	·314
15	34	46·0	·309
20	42	43 9	·310
25	1 48	+ 41·3	0·308

In the northern hemisphere the position of the planet among the stars can be fixed from hour to hour both by the photographic telescope and the heliometer. "The combination of observations," as Prof. Newcomb remarks, "in the eastern and western hemispheres will then, it may be hoped, suffice for the best determination of the solar parallax yet made by direct measurement."

A NEW ALGOL VARIABLE.—Mr. Edwin F. Sawyer describes, in the *Astronomical Journal* (Nos. 448–450), the observations of a variable which he shows to be of the Algol type. The star in question is D.M. + 12° 3557, and has a period of 21h. 21m., the fluctuations in brightness being about half a magnitude, namely, from 7·0 to 7·5. The intervals of time from maximum to minimum and from minimum to maximum occupy individually two hours and a half. The table containing the observations, which Mr. Sawyer has made between September 15, 1895, and October 27 of this year, shows that the star was near its minimum on September 9 and 16, October 3, 10, 11, 12, 20 and 27. Combining these observations with others made at Potsdam, the epoch and period have been approximately determined as 1898 October 3, 13h. 1m. Greenwich mean time, and + od. 21h. 21m. E. respectively. It is not without interest to note that this star, which is No. 2510 of the *Potsdam Photometric Catalogue*, was observed once each by Kempf and Müller on September 24, 1888, as 7·74m., and on October 29, 1890, as 7·57m. On each of these occasions the variable was near a minimum; but as the observations agreed so well, the final value 7·66m. was entered in their catalogue. The magnitude given in the *Durchmusterung* was 7 0.

THE GEMINIDS.—So unfavourable was the weather for meteor observations during last month, that it is very doubtful whether the Leonids and Andromedes were observed at all in England. At the end of this week, December 10–12, there will be a well-known shower emanating from Gemini; but although furnishing us with thirty or forty meteors in an hour, it does not compare with the sometimes magnificent displays that have been set down to the other two meteor swarms above mentioned. The absence of the moon on this occasion should render observations favourable.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

ON Wednesday in last week, being St. Andrew's Day, the Anniversary Meeting of the Royal Society was held in their apartments at Burlington House. The Auditors of the Treasurer's accounts having read their report, and the Secretary having read the list of Fellows elected and deceased since the last anniversary, the President (Lord Lister) proceeded to deliver the anniversary address. After the first part, containing obituary notices of the deceased Fellows, it proceeded as follows:—

The business of the Society during the past year has been fully dealt with in the Report of the Council[1]; and I have little to add to that statement. On the death of Sylvester, it occurred to some admirers of his great mathematical genius that it would be well to create a permanent memorial of him in connection with the Society by founding a medal to be called after his name. The Council, though not disposed as a general rule to add to the numerous distinctions of that character already at their disposal, felt that this was an exceptional case, partly on the ground of Sylvester's great distinction, and partly because, while there are several specialised medals, there is none devoted to the supremely important subject of pure mathematics. They, therefore, expressed their grateful approval of the proposal; and I have now to announce that the fund raised for the purpose being closed, amounting to rather more than 880*l*., a clear capital of 800*l*., together with the dies, will shortly be transferred to the Society. The dies are being engraved after designs by Sir John Evans.

[1] This Report has not reached us.

The help given in this matter by our Treasurer is but a small sample of the multitude of services which he has rendered to the Society during the past twenty years, in addition to the discharge of his official duties. How well these have been performed they only can know who, like myself, have served with him in office. The debt which the Royal Society owes to Sir John Evans has been referred to by the Council in terms of high, though not exaggerated, eulogy. I cannot but add the expression of my personal sense of the deep, I had almost said the irreparable loss which the Society sustains by his retirement.

The question who should be recommended to your suffrages as his successor has engaged the anxious deliberation of the Council. As stated in the report, various considerations have weighed with them. But I feel confident that, as time passes, the wisdom of the decision arrived at will be universally recognised.

Sir George Hamilton has, I believe, done wisely in sending out to India a British Commission, containing a majority of scientific experts, to inquire into the subject of the Plague; and I am glad that so distinguished a Fellow of the Society as Prof. Fraser of Edinburgh has been able to accept the position of Chairman.

The recent sad occurrences at Vienna may suggest the fear that our countrymen engaged in this duty, will be subjected to grave danger. But the disease as it showed itself in Vienna, was of an entirely exceptional form; and if we consider how few of the medical men and nurses who have for a long time past been engaged in actual attendance on plague-stricken patients, have fallen victims to the disease, we may dismiss from our minds the idea of any serious risk to the commissioners.

Their chief duties will, I believe, be to sift and report upon the somewhat heterogeneous and scattered pieces of evidence already published by various observers as to the nature and modes of transmission of the complaint, and the best means of dealing with it. One of the subjects which will engage their attention will be the efficacy or otherwise of the preventive injections of Monsieur Haffkine. On this question our Fellows are likely to have an opportunity of judging for themselves; for Haffkine himself has agreed to come over to this country in May, a time of the year at which his services in India can best be spared, in order to bring his facts before us at one of the "meetings for discussion."

There is no subject in Biology of greater interest at the present time, whether in a scientific or practical point of view, than that of the "serum therapeutics" of infective diseases. According to a recent report, which bears throughout the characters of authenticity,[1] a great success in this direction has been lately achieved. Mr. Chamberlain, whose enlightened action regarding malaria and allied disorders in Africa, has been referred to in the Council's report, consulted the Royal Society about two years ago as to the possibility of devising some means of arresting the fearful ravages of rinderpest among the cattle in the southern parts of that continent. The stamping-out process by wholesale slaughter which, at great expense to the country, formerly proved effectual in England, could not be thought of in South Africa, whose vast regions are sparsely populated, while buffaloes and other animals beyond human control are able to contract and spread the disease. But could nothing be done by modern scientific methods? The subject appeared full of hope, because, as was shown long ago in this country by Burdon-Sanderson, rinderpest resembles small-pox in the fact that one attack, if recovered from, protects against a recurrence of the disease.

Mr. Chamberlain was fortunate in securing, with the consent of the German Government, the services of that distinguished bacteriologist, Prof. Koch. We rejoiced to read the reports of his masterly researches and of the brilliant results which he obtained, promising to effect all that could be desired. The

[1] *Vide* "Rinderpest in South Africa," by John Maberly. *The Lancet*, November 5, 1898.

process which he devised did indeed, as we are informed, save the lives of thousands of cattle. In course of time, however, it turned out that the immunity conferred by it was not sufficiently permanent, while it was attended with some other serious practical inconveniences. Hence it became necessary to seek for some more perfect method. This has been done by a German investigator, Dr. Kolle, who went out to continue Koch's work, acting in co-operation with one whom I am patriotic enough to be pleased to speak of as an Englishman, Dr. George Turner, the Government Health Officer of Cape Colony. Koch had early ascertained that the serum of an animal which had recovered from rinderpest, if injected under the skin of a healthy animal, conferred upon it complete though very transient immunity. This was the basis of the work of Kolle and Turner, who, after a long series of laborious investigations, have, it appears, at length attained their object by simultaneously injecting, at two distant parts of the animal's body, a little of the antitoxic serum, and a dose of the blood of a diseased animal, which, without the serum, would prove certainly fatal. The result is that the beast becomes affected with the disease in a form so greatly modified that it causes as a rule, only slight symptoms, and sometimes none at all; and, though it occasionally proves fatal, it does so in considerably less than 1 per cent. of the cattle subjected to it, contrasting most strikingly with ordinary rinderpest, which kills from 80 to 90 per cent. of those affected. And, just as in the case of vaccination, this modified and mild form of the disease confers protection against it in its most virulent condition; so that even the beasts in which the treatment had produced no symptoms at all remained absolutely unaffected when tested subsequently with a dose of infective material sufficient to kill 10,000 full-grown oxen. This immunity is also of a very lasting character; and, indeed, so far as experience has yet gone, it may be as permanent as that caused by an ordinary attack.

This process was very extensively employed as a prophylactic in the herds of South Africa, during the raging of the epidemic, and with most remarkable success. According to an estimate based on the Cape Government statistics, the effect of the preventive inoculations carried out during the last two years, including those by Koch's method, has been to cause the saving of the lives of upwards of 700,000 head of cattle. It is believed that, had it not been for these prophylactic labours, the number of cattle remaining in the country, instead of being, as now, upwards of a million, would have been little more than 300,000. And it is to be remembered that these are the gross results, including not only those of the present method, but also those of the comparatively imperfect processes that led up to it.

Assuming, as I believe we may, that the report from which these statements are drawn is entirely worthy of confidence, we have here a striking example of beneficent application of science.

Among the many important matters that have come before us during the past year, some in the domain of chemistry seem to stand out as especially striking. One of these is the liquefacton of hydrogen by Prof. Dewar. In previous attempts by Olszewski and himself, drops of clear liquid had been seen which it was supposed were composed of that element; but no one could be quite sure that these were not merely the result of the condensation of other gases which it is extremely difficult to get rid of completely. None could be certain that hydrogen, if liquefied, would not present, like mercury, the appearance of a metal. Dewar, however, after long continued persevering effort, succeeded in producing a liquid in bulk, with well defined meniscus, which, in one of his wonderfully effective vacuum-coated vessels, could be manipulated experimentally, as liquid air had been, allowing at once the determination of some of its physical constants, and liquefying the previously refractory helium, implying a lower temperature than had ever before been attained by man. This achievement is not only of supreme interest in itself but opens up an entirely new field for investigations into the properties of matter.

Liquefied gases have been the means by which Prof. Ramsay has been able to obtain his recent very remarkable results. As chairman of the Chemical Section of the British Association at Toronto he had boldly taken as the subject of his opening address an unknown element, of the existence of which he felt confident from theoretical considerations. He believed that there must exist such a body with an atomic weight intermediate between those of argon and helium. He sought for this element, hoping to find it locked up, like helium, in some mineral, and in other ways tried to discover it. But in a paper presented to the Society early in this year, he was obliged to confess that all his efforts had been fruitless. At the same time in that paper he again expounded his reasons for believing in the existence of the unknown body. He has since adopted a new line of investigation. Having at his disposal a large supply of liquid air, he tried with it the method of fractional distillation; and after allowing the main bulk to evaporate, proceeded to volatilise and test the residue. In this he did indeed find what appears to be a new elementary body, to which he gave the name of Krypton. But so far from complying with his requirements, this gas was found to be much denser than argon; indeed it is thought probable by Ramsay that it has twice its density, and therefore, being, like argon, monatomic, twice its atomic weight. Ramsay, however, had another resource at his command. Aided by Mr. Travers, who has throughout this inquiry most ably seconded him, he had, by long continued labour, procured a large store of argon. This he liquefied by subjecting it to the cold of boiling liquid air; and surmising that any element lighter than argon would be present in the superjacent vapour, he collected this and subjected it to analysis. And now he found what he had so long sought for, a new elementary gas with atomic weight intermediate between those of argon and helium. To this he gave the name of Neon.

But this was not all. As the argon liquefied at the low temperature caused by boiling liquid air, a white solid was seen to be deposited in it, and this remained after all the liquid had evaporated. This solid, on being volatilised and tested, was found to be, as is believed, another new element. This, though very unlike argon in physical characters, possesses a nearly, if not absolutely identical atomic weight; just as some metals with very similar atomic weights differ in their qualities. This element has therefore received the appellation Metargon.

Such is a most rough sketch of two samples of the work of the Society during the past year.

The President then proceeded to award the medals.

The Copley Medal is awarded to Sir William Huggins for his great achievements in the application of spectrum analysis to the heavenly bodies.

His first results in this direction were obtained early in 1864. At the commencement of his labours in his observatory at Tulse Hill, he worked in conjunction with the late Prof. Miller. By visual observation a multitude of lines in the spectra of Betelgeux and Aldebaran were carefully measured, mapped, and compared with those of terrestrial elements. This is notable as being the first application of thoroughly precise methods to the study of the spectra of stars, and as showing the presence of terrestrial elements in them.

On August 29, 1864, Huggins discovered the bright line spectrum characteristic of certain nebulae. This must always be regarded as one of his chief titles to fame. It was an epoch-making discovery, for it established in an unquestionable manner that some of these objects were veritably gaseous. The interest of this work was greatly increased by the fact that, by comparison with the spectrum of terrestrial hydrogen, Huggins showed that one of the nebular lines belonged to that substance.

In 1868, Huggins applied the principle of Doppler to the measurement of stellar movements in the line of sight. He thus originated a department of spectroscopy which has been considered to be perhaps the most instructive application of spectrum analysis to astronomy. Notable results were obtained by Huggins himself in the application of this method, and it has led to many remarkable developments in the hands of other astronomers. By following the course which Huggins originated, wholly new classes of double stars have been revealed, the movements of Algol have been explained, and the mathematical theory of Saturn's ring has been visually confirmed.

The appearance of Winnecke's comet, in the year 1868, gave Huggins the opportunity of studying, for the first time, the spectrum of one of those bodies. He found bright lines in the spectrum of the comet which agreed with those of olefiant gas. Thus he established the fact that carbon was a constituent of comets.

The spectrum of Vega had been photographed by H. Draper, in 1872. In 1876, Huggins obtained a photograph of the spectrum of the same star. He then discovered the remarkable series of hydrogen lines characteristic of the spectra of the class of so-called white stars which includes Sirius as well as Vega. The very beautiful system of hydrogen lines in this ultra-violet

spectrum was described by Huggins to the Royal Society in 1879.

In 1881, Huggins succeeded in photographing the spectrum of Tebbutt's comet, and, availing himself of the various improved appliances which were suggested by his unique experience, he photographed the spectrum of the Orion nebulae in 1882. In 1888, a still better photograph of the same spectrum was obtained by Dr and Mrs. Huggins. There was a special interest about this plate. It showed that certain bright lines were common to the nebula and to the trapezium stars, thus establishing the connection between the stars and the nebulae. Further investigations of the same object were also made in 1889 In that same year the spectrum of Uranus was investigated photographically by Dr. and Mrs. Huggins, and was shown to be essentially solar. In 1890, the chief line in the nebular spectrum was accurately re-determined, and an investigation was made by Dr. and Mrs. Huggins of the spectra of Wolf and Rayet's stars in Cygnus.

The most recent work from the Tulse Hill Observatory has been the investigation of the remarkable ultra-violet lines of calcium, by which the characteristics of these lines in the solar spectrum have been explained.

A sketch of the early history of spectroscopic astronomy was given by Dr. Huggins to the British Association, at Nottingham, in 1866. A review of the same subject a quarter of a century later is found in his Presidential Address at the Cardiff Meeting of the Association in 1891. Reference must also be made to a lecture on the remarkable star, Nova Aurigae, given at the Royal Institution in 1892.

A full list of Huggins's papers, up to the year 1894, is found in Frost's translation of Scheiner's "Astronomical Spectroscopy," published by Ginn and Co., 1894

The Rumford Medal is given to Prof. Oliver J. Lodge in recognition of his researches on radiation and on the relations between matter and ether.

In dealing with the history of the discovery by Prof. Hertz of electro-magnetic radiation, it would be impossible to pass over the work done previously, or simultaneously, by Prof. Lodge, on the surging or oscillatory character of the transmission of electric discharges along wires.

Prof. Lodge gave an account of his observations in his lectures to the Society of Arts, delivered in 1888, which are incorporated in his treatise on "Lightning Conductors and Lightning Guards," published in 1892.

The researches of the English and German physicists were entirely independent, and though the merit of the actual discovery of electro-magnetic radiation belongs certainly to Prof. Hertz, there seems little reason to doubt that Prof. Lodge's experiments would have led him eventually to the same result. Prof. Hertz himself says, in the introduction to his work, "Ueber die Ausbreitung der Elektrischen Kraft": "Inasmuch as he" (Prof. Lodge) "entirely accepted Maxwell's views, and eagerly strove to verify them, there can scarcely be any doubt that, if I had not anticipated him, he would also have succeeded in observing waves in air, and thus also in proving the propagation with time of electric force" (p. 3, English edition).

When the discovery of electro-magnetic radiation was announced, Prof. Lodge at once recognised its great importance, and by his lectures and writings contributed largely to make known to this country the brilliant achievement of Hertz. At the same time, by his experimental investigations, he added considerably to the knowledge of the subject, and materially strengthened the evidence that electro-magnetic waves exhibit similar properties to those which have been for a long time assigned to the ethereal disturbances assumed to constitute the mechanism by which are produced the phenomena of light.

Prof. Lodge's introduction of the "coherer"—an instrument the action of which is based on observations made independently by himself and M. Branly as a substitute for the Hertz "resonator," has increased in a marked degree the facility for reproducing and extending the experiments of Prof. Hertz, and has furnished the means of exhibiting much more conspicuously the results obtained.

More recently Prof. Lodge has been engaged in investigating the phenomena presented by the Rontgen rays, and the circumstances under which these rays are produced. He has also studied the effect on the light emitted from a source placed in a powerful magnetic field, which was discovered by Prof. Zeeman.

In connection with all these branches of inquiry, he has communicated to scientific societies and to periodicals a large number of papers, containing valuable contributions to our knowledge of radiations in ether, and suggestive speculations as to the properties of the ether itself.

With the object of obtaining some information as to the properties of the ether, and of ascertaining whether any mechanical connection can be detected between matter and ether, Prof. Lodge carried out an elaborate series of experiments, of which the record appears in the *Philosophical Transactions*, vols. 184 and 189 The special aim of this research was to determine whether a moving mass communicates any corresponding motion to the ether in its immediate neighbourhood, or, in other words, to determine whether the ether has any apparent adhesion to matter, and possesses any property of the nature of, or analogous to, viscosity.

His method of observation is to divide a beam of light into two of equal intensity, and to cause the latter to traverse in opposite directions an annular space in a steel or iron disc. The two beams are superposed so as to produce interference-bands. If any appreciable motion can be communicated to the ether in the annulus by causing the disc to revolve rapidly round the common axis of the disc and annulus, it is practically certain that some change must be produced in the velocity of the light in the two beams, and this change must show itself by an observable displacement of the interference-bands.

No such displacement was observed with any velocity of the disc which could be attained, nor could any shift of the bands be detected when the annulus in the revolving disc was converted into a powerful magnetic field, or was subjected to strong electrification.

The absence of any noticeable effect upon the light in these experiments is taken to indicate that matter has no appreciable hold upon the ether in its neighbourhood, and that no power of gripping the ether is conferred upon matter either by magnetisation or electrification of the kind employed.

[As it is a condition that a part at least of the work on which a claim to the Rumford Medal can be founded should have been published during the two years preceding the award, a list is appended containing the titles of some of Prof. Lodge's papers which have appeared during 1896-98:—

(1) "Experiments on the Absence of Mechanical Connection between Ether and Matter" (*Phil. Trans.*, A, 1897, vol. 189).

(2) "The Influence of a Magnetic Field on Radiation Frequency" (*Roy. Soc. Proc.*, vol. 60).

(3) "Further Note on the Influence of a Magnetic Field on Radiation Frequency" (*Roy. Soc. Proc.*, vol. 61).

(4) "Note on Mr. Sutherland's Objection to the Conclusiveness of the Michelson-Morley Aether Experiment" (*Phil. Mag.*, vol 46).

(5) "On the Rays of Lenard and Rontgen" (*Electrician*, vol. 46).

(6) "On the Present Hypotheses concerning the Nature of Rontgen Rays" (*Electrician*, vol. 36).

(7) "Further Progress in Radiography" (*Electrician*, vol. 36).

(8) "Rontgen Rays" (*Electrician*, vol. 37).

(9) "The Surviving Hypothesis concerning the X-Rays" (*Electrician*, vol. 37).

Several short notes on subjects connected with Radiation have appeared in NATURE during 1896-98.]

One of the Royal Medals is bestowed upon the Rev. John Kerr, as the author of extremely important experimental researches on the optical relations of electricity and magnetism.

Dr. Kerr has made a name, which will always be remembered in the history of science, by his experiments on the optical effects of electrical and mechanical stress, and on the polarisation of light reflected from the surface of a magnetised body.

His observations on electrical stress were recorded in a series of papers published in the *Phil. Mag.* in 1875, 1879 and 1882, in which he demonstrated the fact that the velocity of polarised light in a body subjected to electrostatic influence is different according as the plane of polarisation is parallel or perpendicular to the lines of electric force.

In these experiments he was led to use mechanically strained glass as an auxiliary apparatus, and in October 1888, he published, in the *Phil. Mag.*, an important paper on "The Birefringent Action of Strained Glass."

In 1877, Dr. Kerr (*Phil. Mag.* [5], vol. 3, p. 321) showed that if plane polarised light is reflected from a magnetised surface, the polarisation of the reflected ray is affected by the

magnetic state of the surface This result was of the highest theoretical interest, and it has been a matter of admiration and wonder to subsequent investigators that Dr. Kerr should have been able to learn so much with the comparatively simple and ineffective apparatus at his disposal.

Both of Dr. Kerr's great researches have been the starting points of numerous inquiries. His experiments on electrical stress have been repeated and extended by Gordon, Quincke, Röntgen, and others, while Fitzgerald, Righi, Kundt, Lorentz, Sissingh, Zeeman, J. J. Thomson, Du Bois, Goldhammer, Drude and Leathem, are among those who have been occupied with the extension or theoretical meaning of his work.

Dr. Kerr's researches rank among the most important of those which have been made since the time of Faraday.

The other Royal Medal is conferred on Mr. Walter Gardiner, who has taken a leading part in what is perhaps the most important recent advance in Vegetable Histology, namely, the discovery that the protoplasm in the tissues of plants is continuous from cell to cell, and not broken up into isolated portions by the cell-walls. His first work on the subject dates from 1882, when he published in the *Quarterly Journal of Microscopical Science* a short paper on "Open Communication between the Cells in the Pulvinus of *Mimosa pudica*." Up to that time protoplasmic continuity in plants had only been recognised in the special case of the sieve-tubes and in the endosperms of three species; and even in these instances the evidence that the connecting threads were really of protoplasmic nature was not, in Mr. Gardiner's opinion, conclusive.

In 1883 he presented to the Royal Society an extensive memoir "On the Continuity of the Protoplasm through the Walls of Vegetable Cells" (*Phil. Trans.*, pt. 3, 1883), in which he demonstrated that this structure is constant in the endosperm, and that it also occurs in various tissues of the plant. Mr. Gardiner at that time thought it probable that the phenomenon might be of universal occurrence, and dwelt on its great physiological significance.

In the meantime other observers took up the subject, and the generality of protoplasmic continuity in plants came to be widely recognised by botanists. Mr. Gardiner, however, was severely critical of his own methods and results, and was not satisfied that the evidence, though conclusive in so many cases, was strong enough to bear the weight of so wide a generalisation. He therefore set himself, within the last few years, to re-investigate the subject, with the aid of more refined processes which he had adapted and elaborated.

The results of his renewed work were communicated to the Royal Society last year, in a paper on "The Histology of the Cell-wall, with special reference to the Mode of Connection of Cells" (*Roy. Soc. Proc.*, vol. 62, p. 100). In this work he shows for the first time, that the connecting fibrils of protoplasm can be demonstrated with certainty in all kinds of vegetable tissues, and he is also enabled to make the important statement that "the threads appear to be present *ab initio*."

Mr. Gardiner has done much good work in other departments of the Histology and Physiology of Plants, notably on glandular structures; on the function of tannin; on protoplasmic contractility; and on the phenomena accompanying stimulation in insectivorous plants. His scientific reputation, however, rests chiefly on the fact that to him, more than to any other investigator, is due the discovery of the continuity of protoplasm in plants—a discovery which essentially modifies our whole conception of vegetable organisation.

The Davy Medal is awarded to Prof. Johannes Wislicenus for his numerous and important contributions to Organic Chemistry, embodied in a series of papers extending over the last thirty-five years, and published in the *Berichte* of the German Chemical Society, Liebig's *Annalen*, and elsewhere. The researches undertaken by Prof. Wislicenus and his pupils, inspired by the zeal of their master, have flowed, almost without intermission during the period mentioned, from the laboratories of Zürich, Würzburg and Leipzig. Among his earlier work may be mentioned his classical researches on the lactic acids, which finally settled the much-debated questions concerning the combination of acid and alcoholic properties in oxy-acids in general. These researches threw much light on the subject of the isomerism of the oxypropionic acids. He ascertained the nature of the action of silver oxide on β-iodopropionic acid, while his improved synthesis of ordinary lactic acid from aldehyde, and of β-oxypropionic acid from glycollic chlorhydrin, established the relations of these acids to their respective radicles, ethylidene and ethylene. His study of sarcolactic acid was a notable contribution to the subject of the optical activity of organic compounds, and resulted in the important discovery for the first time of two substances having a structure of proved chemical identity, and yet possessing different physical properties.

The prominent part taken by Wislicenus in unravelling the reactions concerned in the formation of aceto-acetic ester, and in the application of this compound as a synthetical agent, is well known to all chemists. He devised a practical method for its preparation, and was the first to use the isolated substance as the starting point of synthetical operations. He defined the acid property of the replaceable hydrogen atom in this ester, and its homologues, and devised the now familiar methods for the use of the sodium derivatives in organic syntheses. He discovered the "acid" decomposition of the ester and its derivatives, and established the conditions under which the "ketonic" decomposition could be effected. He utilised his methods for the synthesis of compounds of the most varied types, such as mono- and polybasic acids, both saturated and unsaturated, oxy-acids and ketonic acids, ketones and alcohols.

More recently the name of Wislicenus has become closely associated with discovery in the new field of stereo-chemistry. As early as 1869 he pointed out the insufficiency of the ordinary "constitutional" formulae to explain the isomerism of ordinary and active lactic acid, and clearly stated that the explanation was to be found in the tridimensional arrangement of the atoms in space. Van 't Hoff states that it was this statement by Wislicenus which suggested to him the ideas which culminated in his well-known theory of the asymmetric carbon atom. Wislicenus boldly advocated the introduction of geometrical conceptions into the doctrine of the constitution of chemical molecules, and in his memoir "Ueber die räumliche Anordnung der Atome in organischen Molekulen," published in 1887, he extended the hypothesis of van 't Hoff, and showed how the spacial arrangements could be determined in special cases. The new ideas contained in this memoir had a most stimulating effect on the study of stereo-chemical isomerism. Of his own and his pupils' work in this field may be mentioned investigations of the tolane dichlorides, acetylene-dicarboxylic acid, the butylenes and derivatives of crotonic acid.

The Darwin Medal is given to Prof. Karl Pearson in recognition of the great biological importance of his work upon the Theory of Probability, and its relation to vital statistics. The importance of the theory of probability in dealing with the problems of organic evolution was first seen by Mr. Francis Galton. Prof. Pearson's merit lies in the fact that he has so far extended the mathematical theory of chance as to make it possible to treat generally problems which could previously be dealt with only in a few special cases. Prof. Pearson has shown, in various memoirs published in the *Philosophical Transactions* during the last five years, that the amount and frequency of organic variation, the degree of interdependence between one variable organ and others, the phenomena of heredity, and the intensity of selective destruction can be treated quantitatively by means of his development of the calculus of probability; and he has given examples of the treatment of variation and inheritance in man, and in a number of animals and plants.

A calculus by which the fundamental phenomena of organic evolution can be treated quantitatively provides an engine of biological research of a new and powerful kind, and, as a stimulus to new and more accurate investigation of the phenomena of organic evolution, it is of very great importance. The hypothesis of natural selection has hardly been proved by the direct demonstration of a selective death-rate, except in few and simple cases. The demonstration of such selective death-rate in more complex cases is rendered possible by Prof. Pearson's work. Such demonstration is the natural and logical sequel to the work of Darwin himself, and there is a peculiar fitness in awarding the Darwin Medal to the man who has made it possible.

The Society next proceeded to elect the officers and Council for the ensuing year. The list has already appeared in NATURE (p. 39).

In the evening the annual dinner took place at the Whitehall Rooms. Among the guests of the Society who made speeches were the Lord Chancellor, Lord Kitchener, and Lord Curzon.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The completion of the fiftieth year of Sir George Stokes' tenure of the Lucasian Professorship will be celebrated by the University on June 1 and 2, 1899. Invitations to assist will be issued to distinguished representatives of universities and learned societies, British and foreign. A grant of 400*l*. has been made by the University for the purpose, and it is understood that some permanent memorial of the occasion will be provided.

The Walsingham Medal has been awarded to Mr. J. Graham Kerr, of Christ's College, for his researches on *Lepidosiren*. Mr. A. C. Hill, of Trinity, is *proxime accessit*, and five other essays are pronounced by the adjudicators to be of a high order of merit.

A John Lucas Walker Studentship in Pathology, value 200*l*. a year for three years, is about to be vacant. Candidates, who may be of either sex, are to send in their names to Prof. Kanthack by January 18, 1899.

An Isaac Newton Studentship in Astronomy, value 200*l*. a year for three years, will be filled up next term. Candidates must be B.A.s under the age of twenty-five on January 1, 1899. Names are to be sent into the Vice-Chancellor between January 16 and 26.

The Sheepshanks Telescope Committee report that the erection of the polar-reflecting photographic telescope at the Observatory, with its building and dome, is nearly complete. Dr. Common has provided the mirror, and the object-glass is one of Cooke's triple lenses. The tube and apparatus are by Messrs. Grubb. The adjustments and tests have still to be carried out.

Mr. Shipley and Mr. Cronin are to represent the University at the centenary of the Imperial Military Academy at St. Petersburg at the end of this month.

INFORMATION of two examples of munificence to education and science reaches us from the United States. Mrs. Emmons Blaine has given 250,000 dollars to Chicago University for the establishment of a college for teachers. Miss Anna T. Jeanes has recently presented the Academy of Natural Sciences of Philadelphia with 20,000 dollars, the income to be used for museum purposes.

THE following Scholarships have been awarded in connection with the present Session 1898-99 of the Central Technical College:—Clothworkers' Scholarship, 60*l*. a year, to A. J. Cook; Mitchell Scholarship, 50*l*. a year, to R. H. Collins; John Samuel Scholarship, 30*l*. and free education, to F. C. Hounsfield; Institute's Free-Studentships to R. H. Buckie, A. W. Harrold, and W. H. P. Brounger.

THE *British Medical Journal* states that Mr. Alfred L. Jones has offered the sum of 350*l*. a year to establish and maintain a laboratory in Liverpool for the study of tropical diseases. The laboratory will be opened in association with the Royal Southern Hospital, and a Committee has been formed to carry out the scheme in connection with the hospital and with University College.

THE first number of a new monthly magazine, devoted to the principles and practice of teaching the subjects usually studied in secondary schools—by which is meant all schools, public and private, other than public elementary schools—will be published by Messrs. Macmillan in the middle of January next, under the title of *The School World*. The magazine is not designed to be an educational newspaper so much as a periodical for the publication of articles on methods of teaching, and of notes by experienced teachers on the treatment of difficulties met with in actual school work. Rational methods of teaching will be advocated so far as they are practicable under existing conditions in secondary schools, and articles will be published showing how they can be carried out. Among the contributors to the scientific section of early numbers of the magazine will be Prof. L. C. Miall, on experimental natural history; Prof. G. B. Mathews, on the teaching of algebra; and Dr. Francis Warner, on physical observations of boys and girls in schools. Other scientific subjects to be dealt with are the stars month by month, current geographical topics, and experimental general science.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, November.—The first "Cambridge Colloquium" was held at Buffalo in 1896. In consequence of the British Association holding its meeting in 1897 at Toronto there was no Colloquium held in that year. The second Colloquium was held in the present year (August 22-27), at Harvard University. Two courses of six lectures each were delivered, the lecturers being Profs. Osgood and Webster. The latter gentleman took as his text "The partial differential equations connected with wave propagation"—an abstract of this course is to be given in a future number. Prof. Osgood lectured "On some methods and problems of the general theory of functions." Lecture i. was devoted to Picard's theorem, and the application of Riemann's geometric methods in the general theory of functions. Lectures ii. and iii. discussed the representation of multiple-valued functions by means of single-valued functions of a parameter, treated geometrically by Riemann's methods and also Poincaré's theorem. Lectures iv. and v. dwelt on some recent study of the relation between the properties of a function defined by a power series and the coefficients of that series. The last lecture was on certain Cantor's sets, and their application in a question concerning Cauchy's definition of an analytic function. The lectures are very fully reported, and illustrated with diagrams and bibliographical notes. The "Colloquium" is a very interesting and useful addition to the ordinary meetings of the Society. The above meeting was held at the same time as the American Association for the Advancement of Science held its semicentennial meeting, at which about 900 members were present. The section of mathematics and astronomy was well attended. The committee of the section accepted twelve papers in pure mathematics, thirteen in applied mathematics, and sixteen in astronomy. The titles of these are given, and short abstracts of their contents follow. Interesting notes and a list of recent mathematical publications close the number. The *Bulletin* well maintains the high position it has attained.

American Journal of Mathematics, vol. xx. No. 4, (October 1898).—Sur l'intégration hydraulique des équations différentielles, by M. M. Petrovitch. The author writes: "Tous les intégraphes et les appareils pour l'intégration graphique des équations différentielles, proposés jusqu' aujourdhui, sont fondé sur l'emploi de certains principes cinématiques, p. ex. sur les propriétés des roulettes (*cf.* the Catalogue of Models, Apparatus and Instruments, by W. Dyck, Munich, 1892-3)." He shows briefly that these integrations can be effected in quite another way. "Supposons que l'on fasse immerger un corps solide M plus ou moins profondément dans le liquide contenu dans un vase B. Le niveau du liquide montera ou s'abaissera d'après une certaine loi dépendant de la forme du corps M et du vase B et ces formes une fois fixées, la variation de la hauteur du niveau y, comptée à partir d'un plan horizontal fixe, p. ex. à partir de la face inférieure du vase B ne dépendra que de la distance x entre l'extrémité e de la tige ef et la face inferieure du vase B." The principle is applied to the graphical integration of a certain type of differential equations of the first order. The article is illustrated with a few diagrams.—On the hyperelliptic sigma functions, by H. F. Baker. This memoir, which occupies pp. 301-384, appears to be a brilliant contribution to the literature of the Riemann surface.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 24.—"The Origin of the Gases evolved on heating Mineral Substances, Meteorites, &c." By Morris W. Travers, D.Sc. Communicated by Prof. W. Ramsay, F.R.S.

Conclusions.

It would appear that the only evidence on which the assumption that gases of a permanent character, such as hydrogen, carbon monoxide, nitrogen, helium, and argon, exist in the free state in the mineral substances from which they are evolved on heating, rests on certain observations with regard to the cavities which can sometimes be detected by microscopic examination.

The cavities may be either apparently empty or they may contain liquid, and when the mineral is warmed the liquid

disappears at a temperature which is a few degrees below the critical point of carbon dioxide or of some hydrocarbon. The fact that the critical temperature of the liquid is a little below the point corresponding to carbon dioxide, in the case of a mineral containing that substance is not, however, of very great significance as pointing to the presence of a permanent gas. A small quantity of methane would produce the same result (Kuenen, *Phil. Mag.*, 1897).

Further, although it can be shown that *compact* minerals do enclose carbon dioxide and hydrocarbons, gases which can easily be liquefied, the analogy cannot be extended to gases such as hydrogen and helium in connection with minerals like chlorite, mica, and clevite, which exhibit many cleavages.

On the other hand, there is, as I have endeavoured to show, a considerable amount of evidence in favour of the theory which I have put forward:—That in the *majority of cases* where a mineral substance evolves gas under the influence of heat, the gas is the product of the decomposition or interaction of its *non-gaseous* constituents at the moment of the experiment. The results of such experiments cannot, therefore, serve as basis for speculation as to origin and history of the substances in question.

Geological Society, November 2.—W. Whitaker, F.R.S., President, in the chair.—Sir A. Geikie drew attention to some specimens on the table which had been collected by the Geological Survey from the Silurian rocks of County Tipperary. These contained impressions that bore a close resemblance to flattened and drawn-out graptolites, and others that might be taken for mollusca or phyllopoda enlarged by cleavage. It seemed to him, however, extremely doubtful whether these forms were truly of organic origin. They were exhibited in the hope that the palaeontologists in the Society might be able to throw some light upon them from the zoological side.—Dr. G. J. Hinde exhibited and commented on specimens of Devonian rocks sent by Prof. Edgeworth David and Mr. Pittman from the railway-section at Tamworth, New South Wales, which had been received since their paper was read.—Note on a conglomerate near Melmerby (Cumberland) by J. E. Marr, F.R.S. In this paper the author describes the occurrence of a conglomeratic deposit which shows indubitable effects of earth-movement, not only on the included pebbles, but also on the surface of one of the deposits. The rocks are coloured as basement Carboniferous rocks on the Geological Survey map. Sir A. Geikie remarked that in his opinion the author had completely proved the point sought to be established. The peculiar features of the conglomerate described in the paper were obviously due to earth-movements, and not to glacial action. At the same time, while frankly admitting the explanation of the case now brought forward, he held that conclusive evidence had been obtained of glacially-striated boulders in old geological deposits. Other speakers supported Dr. Marr's view that the surface-features of the stones exhibited were due, not to glacial action, but to earth-movements. The author, in reply, stated that he had brought the case forward simply as an example which might be appealed to in future discussions, as showing exceptionally good indications of the various features produced by slickensiding.—Geology of the Great Central Railway (New Extension to London of the Manchester, Sheffield and Lincolnshire Railway): Rugby to Catesby, by Beeby Thompson.—On the Remains of *Amia* from Oligocene Strata in the Isle of Wight, by E. T. Newton, F.R.S.

Entomological Society, November 16.—Mr. R. Trimen, F.R.S., President, in the chair.—Mr. Tutt showed, for Mr. Herbert Williams, a series of specimens of *Pararge egeria* bred from eggs laid in July. A portion of the brood were forced, and the imagos, which emerged in November and December of the same year, showed marked darkening of the hind margin of the under side of the hind wings, and were of a greyer colour than those which appeared at the normal time. He also exhibited a batch of fifty specimens of *Amphidasys betularia* bred from ova deposited by a female captured in Essex. The progeny ranged from a colour rather lighter than the normal form to a blackish tint almost equal to that of var. *doubledayaria*; all intergrades were represented without sign of discontinuity.—Mr. H. J. Elwes gave an account of a journey undertaken by him in June and July of the present year to the Russian portion of the Altai mountains, partly for sport and partly to investigate the distribution of insects in that region, and the line of demarcation between the Eastern and Western Palaearctic sub-regions. He exhibited samples of 141 species of butterflies taken by himself. Of these many had not been previously recorded from the region, of which the total number of species now stood at 184; his list showed that the lepidopterous fauna had a more European and Siberian character than had been previously supposed, or than Seebohm had found to exist in the avifauna. The number of undescribed species taken was small, but several forms were previously known only from remote localities, such as *Melitaea iduna*, hitherto recorded from the fells of Lapland. Few Heterocera were taken, but among them was the third recorded example of *Arctia thulea*, Dalm.—Dr. A. G. Butler communicated a paper on some new species of African Pierinae in the collection of the British Museum, with notes on seasonal forms of *Belenois*.

Linnean Society, November 17.—Dr. A. Günther, F.R.S., President, in the chair.—Prof. Stewart, F.R.S., exhibited and made remarks on the skull of a fox that was described and figured by Bateson in his work on variation. Both upper canines had divided crowns. He also exhibited the double tusk of an Indian elephant. The tusk was two feet in length, and had a deep groove on its anterior and posterior surfaces. He considered that in both cases the condition was probably due to partial cleavage or grooving of the dental papilla. The President, referring to the exhibition of a somewhat similar tusk at the previous meeting, indicated the points in which the two examples differed.—A paper was read by Mr F. Pickard Cambridge on some spiders from Chile and Peru, collected by Dr. Platte of Berlin. The collection was made during a journey extending from Tumbez, in Northern Peru, down the coast of Chile to Cape Horn, and contained nineteen species, of which seven proved to be new to science.—Mr. Spencer Le M. Moore read a paper entitled "The botanical results of a journey into the interior of Western Australia; with some observations on the nature and relations of the desert flora, and on the probable origin of the Australian flora as a whole." The author briefly sketched the physical and botanical features of the West Australian desert, indicating the parallel of 30° S. as, at least in the Coolgardie district, the dividing line between two subfloras. Flowering takes place almost entirely in spring time, when alone the conditions are favourable to it. Statistics of the desert-flora were then given. These comprise 867 known species, of which 860 are Phanerogams, referable to 319 genera, distributed among 73 natural orders. Of the flora 58 per cent. consist of species ranged under 8 orders, with *Compositae* and *Leguminosae* heading the list, leaving 42 per cent. to be shared between the remaining 65 orders. The author disbelieved the current theory of Scandinavian predominance; and the prevalence in Eastern Australia of forms of Indo-Malayan facies was held to be due, in great measure, not to immigration, but to descent from the primitive Tertiary flora. Moreover, the balance of exchange between Indo-Malaya and Australia in favour of the former area, was considered as coming under the doctrine of chances, and not as implying any inherent superiority of the one flora over the other. While in Europe the Australian, *i.e.* the xerophilous, element was, owing to change in climate, eliminated in favour of the present hygrophilous vegetation, in Eastern Australia the conditions remained as they were in earlier Tertiary times until desiccation set in. He held that this desiccation dates from an earlier period in Western Australia; and that this, together with the isolation of the Western portion of the continent in Secondary times by a sea, and later by stretches of desert, explains the floristic difference between the two halves of Australia. Mr. C. B. Clarke, F.R.S., made some observations on the origin of the Australian flora, and on the dispersal northwards of species from the Antarctic.—The President made some remarks by way of comparing the botanical statistics mentioned by Mr. Moore with the results obtained by zoologists in Australia, both as regards the character and origin of the fauna.

Zoological Society, November 29.—W. T. Blanford, F.R.S., Vice-President, in the chair.—Mr. G. A. Boulenger, F.R.S., exhibited a dancing-stick from New Guinea, to which were attached as ornaments two imperfect skulls of the rare Chelonian *Carettochelys insculpta*, a species previously known only from a single specimen in the Australian Museum, Sydney. Mr. Boulenger also exhibited and made remarks upon a large female specimen of a sea-snake, *Distira stokesi*, which had been caught by Mr. F. W. Townsend in Kurrachee Harbour covered with a thick growth of green seaweeds.—Mr. C. W. Andrews

exhibited and made remarks on some bird remains which had been obtained from excavations at the Lake-dwellings near Glastonbury, Somersetshire, and among which were numerous bones of a Pelecan.—Mr. Oldfield Thomas read a letter which he had received from Señor Ameghino on the subject of the newly discovered mammal *Neomylodon*, giving further information, obtained from the Indians, as to its distribution, characters, and habits.—A communication was read from Dr. E. A. Goeldi on the Amazonian Lepidosiren, in which he recorded the capture of two further examples of this Dipnoan in the island of Marajo. Dr. Goeldi gave a short description of the physical features of the locality in which he had found Lepidosiren—a "pirisal" or papyrus-meadow. He also referred to the live specimen in his aquarium which had recently developed branches on its fore limbs. Dr. Goeldi pointed out the gill-like character of the fore limb, and adduced it as a support to the Gegenbaur theory of limbs. He also suggested the possibility that the so-called fore limb of Lepidosiren is not a true fore limb, but a persistent external gill. This paper was illustrated by the exhibition of three specimens of the Amazonian Lepidosiren, which Dr. Goeldi had forwarded for presentation to the British Museum.—Mr. F. G. Parsons read a paper on the anatomy of adult and foetal specimens of the Cape Jumping Hare (*Pedetes caffer*). In it the different systems—osseous, muscular, nervous, circulatory, digestive, &c.—were described in some detail, and contrasted with the corresponding parts in two Jerboas (*Dipus hirtipes* and *D. jerboa*).—A communication was read from Mr. F. O. Pickard-Cambridge on a small collection of spiders from Trinidad, West Indies. Specimens of six species were contained in the collection, of which three were described as new.—Mr. W. E. de Winton read some notes on the breeding of a female African Wild Ass (*Equus asinus*) in the Society's gardens, and called attention to certain facts as regards her offspring, which gave some support to the doctrine of telegony.—Mr. de Winton also read a paper describing the moulting of the King Penguin (*Aptenodytes pennanti*), as observed in a specimen in the Society's gardens. The author remarked that the specimen in question had lived in the gardens for sixteen months, and during that period had moulted only once.—A communication was read from Dr. A. G. Butler on a collection of butterflies made at Salisbury, Mashonaland, in 1898, by Mr. Guy A. K. Marshall. The collection contained specimens of sixty-five species, which were enumerated. Two new genera (*Torynesis* and *Tarsocera*) and one new species (*Aslauga marshalli*) were described in the paper.—Mr. G. A. Boulenger, F.R.S., read a third report on the additions to the Lizard Collection in the Natural History Museum, containing a list of this class (165 in number), new or previously unrepresented, of which specimens had been added to the collection since 1894.

Cambridge.

Philosophical Society, October 31.—Annual General Meeting.—Mr. F. Darwin, President, in the chair.—The following were elected officers for the ensuing year:—President, Mr. J. Larmor. Vice-Presidents: Mr. F. Darwin, Prof. Forsyth, Dr. Gaskell. Treasurer: Mr. Shipley. Secretaries: Mr. Newall, Mr. Bateson, Mr. Baker. Members of Council: Mr. H. Gadow, Mr. D. Sharp, Prof. J. J. Thomson, Mr. A. Berry, Mr. Wilberforce.—On the evaluation of a certain determinant, which occurs in the theory of statistics and of elliptic space, by Mr. A. Berry.—(1) Metrical relations between linear complexes, by Mr. J. H. Grace. In this paper are discussed the metrical relations which exist between the mutual moments and pitches of systems of four, five and six linear complexes. Some of the results are applied to a geometrical representation of a four-system of screws. (2) Apolar systems of quadrics.—Certain systems of quadratic complex numbers, by Mr. A. E. Western.—On Mittag-Leffler's theorem, by Mr. H. F. Baker.—The connection between the chemical constitution of a gas and the ionisation produced in it by Röntgen rays, by Prof. J. J. Thomson. The measurements of the ionisation produced by Röntgen rays in fourteen gases showed that the ionisation was connected with the chemical composition in a very simple manner. The ionisation was found to be an additive property.—On convection currents, and on the fall of potential at the electrodes in conduction produced by Röntgen rays, by Mr. J. Zeleny. During conduction through a gas exposed to Röntgen rays, convection currents are set up in the gas. When two parallel, plane electrodes are used, the motion of the gas begins symmetrically from the centre towards each of the plates. The motion is conveniently made visible by particles of ammonium chloride formed in the gas from ammonia and hydrochloric acid. Screening from the rays the space next to one of the electrodes increases the strength of the convection currents on that side. The cause of these currents is attributed to the motion through the gas near the electrodes of an unequal number of the two kinds of ions by means of which the conduction takes place.—On velocity of solidification, by Mr. H. A. Wilson. The relation between the velocity of solidification of a super-cooled liquid and the super-cooling has been investigated for a number of substances by G. Tammann and Friedländer (*Zeitschrift P. C.*, xxxiv. p. 152, 1897, and xxiii. p. 326, 1897). Assuming that the rate of solidification is directly proportional to the difference between the internal pressures in the liquid and solid and inversely proportional to the viscosity of the liquid, the velocity of solidification can be expressed by a simple formula.

November 28.—Mr. J. Larmor, President, in the chair.—(*a*) On the flame spectrum of mercury and its bearing on the theory of the distribution of energy in gases, by Prof. Liveing. The author had found that mercury heated in a flame of cyanogen, burning in oxygen, emitted at least two rays, at wave-lengths 2535 and 4358, which he had been able to photograph. The vibrations producing these rays must, he thought, be the result of a direct change of heat into vibratory energy; and if so, the ratio of the specific heats of mercury, at constant pressure and constant volume, proved only that, at the temperature of the compressed vapour in a sound wave, no very sensible proportion of the heat is converted into vibratory motion, though at a higher temperature a sensible proportion is so converted. This appears to negative the hypothesis that energy is always distributed equally in all the degrees of freedom of the molecules, as well as the assumption that a gas having 1·66 for the ratio of its specific heats must have monatomic molecules. (*b*) On the variation of intensity of the absorption bands of different didymium salts dissolved in water, and its bearing on the ionisation theory of the colour of solutions of salts. The author exhibited a series of photographs of the absorption bands produced by equivalent solutions of didymium nitrate and chloride, of which the strength was regularly graded, and the absorbent thickness varied.—Note on the vapour of iodine, by Prof. Dewar. The author had found that by careful distillation in vacuo films of iodine could be made so thin as to transmit light and exhibit the colours of thin plates by reflection. He exhibited experiments showing that at ordinary temperatures pure dry iodine emits vapour which, in a half-litre flask containing air, is sensibly coloured, whereas in similar circumstances, except that the air pressure was reduced, the colour is much less. This difference is enhanced as the temperature rises, so that at 100° it is very marked in a tube of only 1 cm. diameter.—On the partitions of numbers which possess symmetrical graphs, by Major Macmahon, F.R.S.

Manchester.

Literary and Philosophical Society, November 15.—Mr. J. Cosmo Melvill, President, in the chair.—Dr. G. H. Broadbent described the development and life-history of *Vorticella putrina* by means of thirty-four diagrams made from his own investigations. The cyst is circular in shape, the contents being finely granular, and the only indication of life is given by the contractile vesicle. This at first contracts at rare intervals and very slowly, and after a time an oral canal appears which gradually becomes more distinct, whilst the contractions of the vesicle grow more frequent. When the vorticella emerges from the cyst, a small portion is at first protruded through a very small aperture in the cyst-wall, in shape like a bladder, this gradually increasing in size until the whole creature has emerged, the aperture meanwhile appearing not to increase in the least. It is remarkable that after full extrusion the cyst-wall remains as large and as circular as before, whilst the organism is much larger than the cyst, and the vesicle greatly increased in size, thus indicating that the creature has been under great pressure in the cell. After emerging, the vorticella may remain quiescent for a time, until the basal cilia are developed, when it swims rapidly away as a "free-swimming" form. It afterwards attaches itself by the basal portion to some foreign body, and begins to shoot out a stalk which increases in length, while cilia are developed at the oral end. "Detached" as distinguished from "free-swimming" forms

were described, and it was shown that the development of basal cilia was always identified either with attachment to or detachment from the stalk.

DUBLIN.

Royal Dublin Society, November 16.—Mr. W. E. Wilson, F.R.S., in the chair.—Sir Howard Grubb, F.R.S., Vice-President of the Royal Dublin Society, read a paper on the correction of errors in the distribution of time signals. After referring to the various methods that are in use for the purpose of time distribution and the difficulties to be overcome, he described a system which he had recommended for a large institution in England, in which the conditions were somewhat similar to those of the Royal Dublin Society, though on a very much larger scale. He proposed that the best regulator clock should be procured and made to serve as the controlling clock of the whole system, which, however, would be further checked once every twenty-four hours by a signal from Greenwich, this being very much the same system as adopted at the Royal Dublin Society. The controlling clock, however, in this case he proposed should be sealed up in an air-tight case and in an atmosphere of nitrogen, and this placed in an outer case, or jacket, also containing nitrogen. By this means a constant pressure can be kept in the inside case, and with due precautions such a clock can be kept under conditions of constant pressure and temperature, and therefore should be expected to give extremely good results. This clock is then used to control a piece of uniform motion clock worked by a device very similar to what he has adopted with such success for his astronomical instruments, which has now been tested for several years and given excellent results. This piece of uniform motion clock is further checked by the Greenwich signal, it being supplied with a device by which the services of a human being to receive the signal and correct the clock are dispensed with. By an automatic arrangement the signal is received by this clock and corrected by exactly the amount it varies at that moment from the true time, and further a register is made of the amount of that correction, which can be afterwards inspected and noted. This uniform motion clock then serves as the central or distributing clock for some 200 other clocks spread throughout the building, which are practically only dials worked from this distributing clock.—Prof. G. A. J. Cole exhibited a method of intensifying the coloration imparted to a Bunsen flame by potassium in silicates. The minute assay is decomposed in a bead of sodium carbonate, as described in the *Geological Magazine*, March 1898. The method is of service in estimating the nature of the undifferentiated ground mass in many igneous rocks.

PARIS.

Academy of Sciences, November 28.—M. Wolf in the chair.—On the relation which exists between the progressive motion and the motion of inclination in the safety bicycle, by M. J. Boussinesq.—A differential method for determining variations of latitude and the constant of aberration, by M. G. Bigourdan. The method described is purely differential, and hence the results are free from errors inseparable from absolute measurements. It is independent of the stability of the telescope, and since only zenithal stars are employed, practically independent of refraction.—On the measurement of small diameters, by M. Maurice Hamy. The application of the interference method of Fizeau and Michelson is difficult for faint stars, the bands being scarcely visible. In the modification suggested the slits have a width which is appreciable compared with the distance of their centres, and hence the formula of Michelson is inapplicable. An approximate formula for the method thus modified is developed by the author. On some types of partial differential equations of the second order, by M. E. Goursat.—On orthogonal systems, by M. Tzitzéica.—On the complex multiplication of Abelian functions, by M. G. Humbert.—The mechanical equivalent of heat and the specific heats of gases, by M. A. Leduc. An application of the formulae developed in previous papers to determination of J from air and carbon dioxide. The deviations found are very large, and are due to the difficulty of measuring accurately the specific heat at constant pressure of a gas. The inverse calculation of this latter constant from the experimental value of the mechanical equivalent would probably be the better application of the formulae.—On condensed oxides of rare earths, by MM. G. Wyrouboff and A. Verneuil. The power of polymerising with great ease under a variety of conditions is especially characteristic of the ceroso-ceric group of oxides, and many reactions in this group can be more satisfactorily explained by this hypothesis than by the assumption of the formation of basic salts.—Observations on the spectra of aluminium, tellurium, and selenium, by M. A. de Gramont.—On the aromatic urethanes of tetra-hydroquinoline, by MM. Cazeneuve and Moreau. The urethanes were obtained by the action of an excess of tetrahydroquinoline upon the carbonates of phenyl, ortho-chlorophenyl, methoxy-phenyl, and α-naphthol.—On pulegenacetone, by M. Ph. Barbier.—Action of potash upon oxynitrocellulose, by M. Léo Vignon. The chief product of this reaction is oxypyruvic acid, $CH_2.(OH).CO.CO.OH$.—On a new crystalline principle extracted from *Artemisia absinthium*, by MM. Adrian and A. Trillat.—Researches on the means of increasing the adhesive power of copper solutions used for spraying diseased vines, by M. Joseph Perraud. Of the various substances tried, colophane proved to be by far the most effective, soap being the next useful.—Composition and food value of cheese, by M. Balland.—On a method of colouring living protoplasm by the pigments of fungi, by M. L. Matruchot.—Influence of anaesthetics on the formation of chlorophyll, by MM. E. C. Teodoresco and Henri Coupin. Chloroform or ether prevent the production of chlorophyll in etiolated plants exposed to the light. Used in quantities too small to completely prevent the formation of chlorophyll, the production of the green colouring matter was greatly retarded.—Geobotanical study of the flora of the high basins of the Sallanche and Trient, by M. Paul Jaccard.—On the discovery of fossils in the layers constituting in Provence the formation called *étage de Vitrolles*, and on the limit of the Cretaceous and Tertiary beds in the basin of Aix Bouches-du-Rhône, by M. G. Vasseur.—Measures proposed to avoid collisions at sea, by M. E. Lacoine.—Remarks concerning the green ray, by M. Piot-Bey.

NEW SOUTH WALES.

Royal Society, September 7.—Mr. G. H. Knibbs, President, in the chair.—Key to tribes and genera of Melanospermeae (olive-green seaweeds), by R. A. Bastow.—A study of the dialects of New Caledonia, by Jules Bernier, curator of the Musée Néo-Caledonienne. No less than twenty dialects are distinguished in New Caledonia, which are grouped into the following main divisions: the Southern, inclusive of the Isle of Pines; the Central; the Northern; and those parts of the Loyalty Islands peopled by Melanesians.—An interesting collection of photographs from the Don Dorrigo and Brush districts, New South Wales, chiefly geological, were shown by his Honour Judge Docker.—A new Eucalyptus oil was exhibited by Messrs. Baker and Smith of the Technological Museum, Sydney. On rectification this oil was found to contain a fraction boiling between 280°-290° C., equalling 18 per cent. of the whole, and which consisted almost entirely of eudesmol, comparatively in a pure condition. The fraction wholly crystallised in less than one hour.—The latest type of polariscope (Wright-Newton projecting polariscope) was exhibited by Dr. F. H. Quaife.

Linnean Society, October 26.—Prof. J. T. Wilson, President, in the chair.—On *Carabidae* from West Australia, sent by Mr. A. M. Lea (with descriptions of new genera and species, synoptic tables, &c.), by Thomas G. Sloane.—Descriptions of new species of Australian Coleoptera. Part v. by Arthur M. Lea.—A statistical note on variations in the flowers of *Anguillaria dioica*, R.Br, by C. T. Musson. As is well known, *Anguillaria dioica*, R.Br. (N.O. *Liliaceae*), is widely distributed in extra-tropical Australia and Tasmania, and occurs under three forms—with male flowers only (without even rudimentary pistils), with female flowers only (without even rudimentary stamens), and in a polygamous condition (with male, and hermaphrodite flowers). But whether or no all three forms occur together throughout the area of distribution, and if so in approximately what relative numerical proportions are matters not ascertainable from present records. From the data collected it would appear that in the locality mentioned the tendency towards the condition of dioecism has reached an advanced stage.—Mr. North exhibited the skin of a fledgling fan-tailed cuckoo, *Cacomantis flabelliformis*, which he had caught on October 3 in a gully at Chatswood. It was being fed by its foster parents, a pair of rock warblers, *Origma rubricata*, whose nest was found in a dark recess in the rocks a few feet away. Usually the egg or young of this parasite is found in domed nests built in situations which are more or less exposed to the

sun's rays. That it is not a solitary instance of this cuckoo depositing its egg in the nest of this gloom-loving species is borne out by the fact that the same pair of rock warblers built again in a rocky chamber about two hundred yards away from their previous nesting site

HINDU MANNERS AND CUSTOMS.

Hindu Manners, Customs and Ceremonies. By the Abbé J. A. Dubois. Translated from the Author's later French MS., and edited with notes, corrections, and biography by Henry K. Beauchamp. With a Prefatory Note by the Right Hon. F. Max Müller, and a Portrait. Pp. xxxvi + 730. (Oxford: at the Clarendon Press, 1897.)

THE work of the Abbé Dubois, both in the original French, and in the English editions—the one published in 1816, the other some thirty odd years ago—has long been a standard work on modern Indian customs, much valued and frequently quoted by ethnologists. But strange to say, what has hitherto been known as the Abbé's work is in fact merely a rough sketch and (as Mr. Beauchamp says) "only an extremely poor representation of what the Abbé's great work really was." The history of the book is peculiar. The French MS. of the original draft was placed in the hands of Major Wilks in the year 1806, when the Abbé had been about fourteen years in India. Major Wilks studied the work, and on his recommendation the MS. was, in 1807, purchased by the Madras Government and transmitted to London for translation and publication. Yet the English translation was not published until 1816. In 1815 the MS. was returned to the Abbé, and he "put into it all the additions and corrections suggested by many years of additional study and investigation; and when he sent it back to the Government of Madras, it was, practically speaking, a different work altogether." However, neither this revised MS., nor a finally corrected copy prepared by the Abbé three years later, have ever been used for the editions hitherto published, although both MSS. were sent to England and preserved in the India Office Library. One copy of the finally revised MS. was left in the records of Fort St. George, and this has now been translated and edited by Mr. Beauchamp, so that at last we possess the Abbé's work in its final and corrected shape.

The work of the Abbé Dubois is vastly superior to the ordinary accounts of travellers and missionaries in India. Few Europeans have succeeded in obtaining so much valuable information concerning the life of the natives as the Abbé. The secret of his success is best told in his own words (p. 10):

> "I had no sooner arrived amongst the natives of India than I recognised the absolute necessity of gaining their confidence. Accordingly I made it my constant rule to live as they did. I adopted their style of clothing, and I studied their customs and methods of life in order to be exactly like them. I even went so far as to avoid any display of repugnance to the majority of their peculiar prejudices. By such circumspect conduct I was able to ensure a free and hearty welcome from people of all castes and conditions, and was often favoured of their own accord with the most curious and interesting particulars about themselves."

That he went about in this way, and identified himself, as it were, with the people, makes the Abbé's account of Hindu manners, customs, and ceremonies so very valuable even in the imperfect form in which it has been known for years, and of course all the more valuable in its final and corrected form as presented to us by Mr. Beauchamp. Times have changed, no doubt, since the days when Abbé Dubois wrote. But Mr. Beauchamp is certainly right in saying that the work is "as valuable to-day as ever it was; even more valuable in some respects." For although the Abbé's work is merely an account of the inner life of the Hindus as seen and studied by him at the beginning of this century and in a limited area, viz. the country that lies south of the Vindhyan range, yet the broad facts of Hindu religion and sociology, as recited by the Abbé, are to a great extent true for a much wider area, and they are extremely instructive when compared with the facts known from ancient Hindu literature on the one hand, and with the manners and customs of the present day on the other.

Mr. Beauchamp has added some very valuable notes which go far to prove that the Hindu character is not quite as unprogressive as it is generally imagined to be, that even in India civilisation is not at a standstill, but that some progress has been made even within the short space of seventy or eighty years. On the other hand, if we compare the Abbé's account of Hindu life with what we know from ancient Hindu literature (and our knowledge of *ancient* Hindu life has become infinitely more accurate and comprehensive than it was when the Abbé wrote), we are constantly startled by the tenacity with which ancient customs survive in India. And for this very reason the Abbé's description is of inestimable value for the student of ancient India.

The most valuable parts of the book are those in which the author relates what he has seen himself. The Abbé is a shrewd and patient observer, and his account is full of the most interesting information about caste divisions, religious ceremonies and superstitions, about witchcraft, social customs, especially marriage rites (pp. 214–235), burial and mourning customs (pp. 321 *sq.*; 354 *sqq.*; 488 *sqq.*), about the status of women (pp. 315 *sqq.*, 339–370, &c.), infanticide, customary law, snake worship, cattle worship, &c. The Abbé has even a vague idea of what is now called comparative mythology (*cf.* p. 550 *sqq.*).

But what he relates, not from his own observation, but from literary documents (written in Sanskrit or Tamil), must be used with great caution, and should be compared with more recent and authentic publications, such as the works on Hindu law and ritual translated in the "Sacred Books of the East." The books from which the Abbé derives his information are mostly modern compilations of a sectarian character. Thus, the "Nittia-Karma" (rather "Nityakarma"), from which the author quotes largely (p. 238 *sqq.*), is evidently a text of the Vaishnava sect, and many of its details would not be applicable to members of other sects.

It must also be borne in mind that the Abbé is a Christian missionary, and his judgment is by no means unbiased. His strictures on the Hindu character are certainly most unfair, and his wholesale condemnation of the Brahmans as a class cannot be accepted by any serious student. Our acquaintance with the history of civilisation in India enables us to gain a far more favourable view, both of the moral and intellectual development of the Hindu nation. To quote only one example. What the Abbé says (p. 380 *sqq.*) about the learning of the

H

Brahmans, contending that they have not systematically cultivated learning, and that they have not made any appreciable progress in its pursuit, is absolutely false in the light of our present knowledge of Sanskrit literature. A mass of scientific literature (on grammar, astronomy, medicine, philosophy) is there to contradict such a statement.

The Abbé's knowledge of Buddhism is derived from very secondary sources—evidently from accounts given by the most passionate opponents of the Buddhists. Hence he speaks of "this odious doctrine" of "pure materialism," and of "this abominable school" (p. 415) with utter contempt. Had he known Buddhism from its own literature, and been able to acquaint himself with Buddhist ethics, or had he known only the older and purer Sanskrit literature (which, indeed, in his days was scarcely accessible), his judgment of the moral character of the Hindus would probably have been less partial, and his picture of the Hindus as a nation would have shown brighter features than is the case now.

The editor and translator has performed his task very creditably. We should only have wished that the Sanskrit quotations had been given in a more correct form, and a more modern spelling of the Sankrit names and terms substituted for the spelling used by the Abbé. The index (of six pages to 724 pages of text!) is rather too meagre for a work of such an extent, and treating on such a variety of subjects. But these are minor faults in a work for which every Indologist and Ethnologist will be thankful.

M. WINTERNITZ.

FOSSIL PLANTS.

Fossil Plants for Students of Botany and Geology. By A. C. Seward, M.A., F.R.S., F.G.S. Vol. i. Pp. xviii + 452. (Cambridge University Press, 1898.)

THE botanical side of palaeontology has been passed over in general treatises and text-books in a manner that shows the authors had little, if any, personal knowledge of fossil plants. This has been due to the want of any trustworthy elementary manual on the subject. Mr. Seward's admirable book, of which only the first volume is published, will supply this want. Though addressed to students of botany and geology, it must be regarded mainly as a guide to palaeobotany for the benefit of the former, since no one not well versed in botany could follow the technical descriptions of such structures, for examples as the Calamites. On the other hand, introductory chapters on geology and the conditions under which fossil plants are preserved, enable the botanical student to read the book with no previous study of geology.

Mr. Seward, while not going so far as the late Prof. Williamson, who would diagnose no fossil plant which did not exhibit internal structure, lays great stress on the pitfalls in the way of those who have to determine fossil plants in which no structure is preserved. The group of jointed stems on p. 95, belonging to Cryptogams, Gymnosperms, Monocotyledons and Dicotyledons, is scarcely a happy illustration of the danger of trusting to superficial resemblances, since hardly any one at the present day would be likely to base determinations on such material without collateral evidence. In collecting and studying fossil floras, if these are at all extensive, it is easy to perceive whether they are from damp or dry statior from temperate or warm climates, and so on; and suc considerations would materially help in ascertainin whether Equisetum or Casuarina and Ephedra would l likely to be present. The worker, however, is rare obliged to rely on isolated leaves or twigs, and an e amination of the matted masses in which Equisetum usually fossilised, is convincing as to the real nature the plants. In dealing with late Cretaceous and Tertiar plants it may be well to remember that continental floras now held to be indigenous to certain regions, have for merly been migratory over wide areas, and are probabl now but sojourners on the spots they occupy. The gener composing them were associated together in the pas much as they are now, a fact that may assist in thei determination. Floras of oceanic islands have probabl been indigenous from remote periods, as with the Tertiar plants of Madeira, which comprised few exotics.

Palaeontologists may hardly agree as to the propriet of adding the terminations "ites" or "opsis" to recen genera when they have been proved to have existed i the fossil state, unless the nomenclature of plants is t differ from that of animals, otherwise we should hav Nautilites, Terebratulites, Ostreites. Such termination are more useful when implying doubt as to the actua identity of the recent and fossil genera. These, how ever, are minor matters, and the introductory chapter are on the whole so lucid and sufficient, presenting al requisite information in so concise and reasonable a manner, that there is little room for criticism.

Almost 300 pages of the first volume are devoted to the "systematic" description of fossil plants, beginning at the lowest and leaving off in the midst of vascular cryptogams. The lowest forms of plant life, unless partly siliceous or calcareous, are rarely preserved, and are of little interest to the geologist or palaeontologist. The completeness with which even the largest seaweeds decay, especially the brown algae, leaves little hope that many can have been preserved; and there can only be one opinion as to the wisdom of discarding all problematical markings. The ancient and gigantic Nematophycus is almost the only one determined with certainty. It was remotely allied to Laminaria, and is met with in Silurian and Devonian rocks. The Diatoms, so far, do not appear to be more ancient than the Lias. The Siphoneae are a group of exceptional palaeontological interest, and though most of the Caulerpites of old authors are passed over, the minute and often beautiful calcareous organisms so familiar to collectors of Eocene mollusca receive adequate attention. The very ancient Corallinaceae, the plant nature of many of which has only recently been admitted, are fully dealt with, and the extensive part they are now known to have played as reef-builders is recognised. The Characeae form a distinct group, the Charophyta, the fruits of Chara, so abundant in the Eocenes, first definitely appearing in the Jurassics, if not indeed in Palaeozoic rocks.

The fossil Hepaticae are of little interest, being so poorly represented in the fossil state, and of those recorded the author scarcely accepts any except the Marchantites of Sezanne and some of the fragments preserved in amber. Though it seems so probable that mosses must have been well represented in carboniferous

forests, no unmistakable specimen of that date has yet been discovered.

The concluding chapters are devoted to vascular cryptogams, over 140 pages being assigned to the Equisetales, chiefly to the remarkable group of Calamites, which must have been so conspicuous an element of carboniferous vegetation. Though cryptogamic, they formed large trees forty or fifty feet high, with woody trunks of exogenous growth. For this reason a section of the Calamites named Camelodendron have been and are even yet regarded as Gymnosperms by some French writers. The genera and species of this group are peculiarly difficult to diagnose, every organ being detached and preserved in a different manner. Internal casts of pith cavities in sandstone are the most familiar objects, but the more valuable specimens are those which preserve their internal structure, so ably deciphered by Williamson and others. The foliary organs are found separately in the shales and ironstone nodules; and the strobili in various conditions, which have permitted their internal and external structure to be examined. The roots of several kinds are also found detached from the stems. The author, without attempting to unite these scattered organs into specific wholes, has grouped the facts in the clearest manner. The variety presented prove that several distinct generic types existed, and as each variety of each separate organ was first described in ignorance of its probable relationship to the other, a complicated nomenclature has resulted. The Calamites, well represented in the Devonian, did not survive the Permian, though represented in the newer rocks by the closely related Equisetum.

The second important carboniferous group, Sphenophyllum, is also placed in a separate class, the Sphenophyllales, as a type that cannot be assigned to any existing group. Its leaves are wedge-shaped, with one or several veins and disposed in whorls, the strobili long and narrow, and the stem slender and woody. It was possibly a climbing plant, and is regarded as linking the Calamites and Lycopods.

In so brief a notice it is difficult to do justice to a work so full of matter and observation. Botanists and geologists must equally congratulate themselves on having so obscure and difficult a subject put before them for the first time in a really lucid and comprehensive manner.

J. S. G.

INFINITESIMAL CALCULUS.

Infinitesimal Analysis. By William Benjamin Smith. Vol. i. Pp. xvi + 352. (London: Macmillan and Co., Ltd., 1898.)

IT may be assumed that the contents of this volume represent, on the whole, the author's conception of a reasonable first course for the average University student. Judged from this point of view, the work certainly deserves approval, and is a favourable specimen of the class to which it belongs.

In the first two chapters the processes of differentiation and integration are explained, with appropriate graphical illustrations. No attempt is made to discuss all the subtleties which modern function-theory has shown to be involved in the assumption of the possibility of differentiation and integration, but the analysis, so far as it goes, is sound, and something is done to guard the student from making false generalisations.

The next four chapters deal mainly with applications. These have been judiciously selected, and are of practical importance as well as theoretical interest. Kinematical applications might have been advantageously included; in fact, considering the general character of the book, it is strange that kinematical considerations have been almost entirely ignored.

Chapter vii., on partial integration, concludes with Green's theorem; it is a pity that Stokes's theorem was not also included. A short but useful chapter on definite integrals, and another on curve-tracing, conclude the volume.

On pp. 18–20 there are some remarks about velocity with which we profoundly disagree. After allowing that "according to the most familiar notions" $\Delta s/\Delta t$ "is the *average speed* (or velocity) during the time Δt," and that "if the space be a function of the time" (it is difficult to see how any other assumption could be made) then in general $\Delta s/\Delta t$ has a definite limit ds/dt when Δt becomes infinitesimal, Prof. Smith proceeds:

> "Mechanically, however, this limit is not itself an average speed at all, it is not of the same nature as the variable difference-quotient $\Delta s/\Delta t$. For this quotient *never* assumes this limiting value, no matter how small Δt be made. And this is quite what we should expect and what the nature of the case demands. For motion implies duration, however small, of time, and change, however small, of place. When there is no lapse of time and no displacement there is no motion, and hence no speed (or velocity). In all strictness, there can be *no motion at an instant* and hence no *speed* (or velocity) *at* an instant. The concept of speed (or velocity) or motion will not combine with the concept of instant (or point of time) to form a compound concept."

Surely Prof Smith has here confounded the concepts of motion and displacement. If we allow that motion at an instant is impossible, how are we to escape Zeno's paradoxical conclusion that all motion is impossible? How can I move from one place to another during a minute, say, if *at every instant* of that interval motion is impossible? The remark, later on, that "this limit of the average velocity, characterises not the action but the state of the body, and is itself *not* a velocity though everywhere named so," does not improve matters, and is really irrelevant. The definition of velocity is quite independent of such question-begging terms as "action" and "state." Each of these terms, as applied to velocity, is just as good and just as bad as the other: it is when we add the words "of the body" that the metaphysical difficulty comes in, on account of the relativity of motion. But assuming that we can form a clear concept of a continuous displacement expressed by a law $s = f(t)$, there is neither a logical nor a metaphysical difficulty in proceeding to $\dot{s} = f'(t)$ and saying that this is the velocity at time t, if we have already agreed that when $s = at + b$, the velocity is a (a, b being constants): that is, in whatever sense a measures the velocity for the law $s = at + b$, then *in precisely the same sense* $f'(t)$ measures the velocity at time t for the law $s = f(t)$.

Another passage to which we feel bound to call

attention is example 18, p. 229. Here the analysis really solves the problem of finding when $(\alpha+1)(\beta+1)\ldots(\lambda+1)$ is a maximum subject to the condition that $a^\alpha b^\beta \ldots l^\lambda = N$; $a, b, \ldots l$, N being given quantities. But the heading of the article is, "How must the prime factors of a number enter into it that it may have as many divisors as possible? (Waring)," a question from which we have vainly tried to extract any meaning whatever, and with which, in any case, Prof. Smith's analysis cannot have anything to do. G. B. M.

OUR BOOK SHELF.

Die Optik der elektrischen Schwingungen. (Experimental Investigations on Electro-magnetic Analogies of the most important Optical Phenomena.) By Prof. A. Righi. Translated into German, with additions by the author, by B. Dessau. Pp. xi + 267; with 40 illustrations and figures. (Leipzig: O. R. Reisland, 1898.)

THOSE to whom Prof. Righi's Italian edition of last year was not accessible, will welcome this German translation of his interesting book. The reproduction, by means of electro-magnetic waves, of some of the more complex optical phenomena, necessitates the use of an oscillator which gives out a series of waves that do not decrease too rapidly in intensity, and that are considerably shorter than those used by Hertz in his experiments.

Prof. Righi has carried on a number of investigations with such oscillators which emitted waves ranging upwards from 2·6 cms. in length, and the present volume is devoted for the most part to an account of this work.

The first part deals with a detailed account of the construction and use of his oscillators and resonators, and with the secondary waves due to the presence of the receiver and neighbouring bodies. These effects are studied first, in order that they may not lead to misinterpretations in the later results.

In the second part the electro-magnetic analogies of many optical phenomena are considered.

The working details of the experiments are given, and the difficulties attending them are pointed out, thus enabling one to reproduce the effects with the least amount of trouble.

Two investigations which have appeared since the publication of the Italian edition are then appended, and the last part of the book consists of mathematical additions on various topics connected with the subject in hand.

The book is written in an able manner, and conveys to the reader a clear idea of the properties of electrical waves, and Prof. Righi's method of manipulating them.

J. Z.

Calculations in Hydraulic Engineering. By T. Claxton Fidler, M.Inst.C.E., Professor of Engineering, University College, Dundee. Part i. Pp. xii + 155. (London: Longmans, Green, and Co., 1898.)

THIS is the first part of an extended treatise, and it discusses Fluid Pressure and the Calculation of its Effect in Engineering Structures. The treatment of the subject is refreshing and stimulating, by contrast with the arid methods of our scholastic text-books. The illustrations of the abstract theory are taken from actual problems on a large scale, which appeal to the engineering student, to whom this treatise is addressed. A striking novelty is the discussion in Chapters iv. and vi. of the buckling tendency in straight pipes under uniform fluid pressure. Although the material of the pipe carries no longitudinal thrust, the conditions of stability are exactly the same as in Euler's theory of the bending of a column. This paradoxical fact is discussed theoretically, and its experimental verification is described in an Appendix. Chapter v. is on Fluid Arches, and shows how the pressure in a main, forming a tubular arch, can be used to assist the stability. We are reminded of Prof. Fitzgerald's suggestions of inflated structures and columns, and the pneumatic system of architecture, in which the strength is kept up by compressed air, pumped in at intervals as required, as in the tires of our bicycles. A short account of Prof. Fitzgerald's theory will be found in the recent edition of Perry's "Applied Mechanics." Chapters viii. and ix. treat of the equilibrium and stability and bending stresses of floating bodies, not from the point of view of the Naval Architect, but as required by the Civil Engineer in the design of pontoons, bridge-caissons, and gas-holders.

The diagrams are carefully drawn to represent some real actual construction, and the illustrative examples are worked out to their numerical conclusions, an essential part of the theory for the engineering student, although so completely ignored in our academic treatises. G.

Birds of the British Isles. By John Duncan. Pp. xvi + 448; illustrated. (London and Newcastle: Walter Scott, Ltd., 1898.)

THE excellent illustrations and brief descriptions of British birds published in the *Newcastle Weekly Chronicle* met with such a favourable reception, that the author has considered it advisable to reproduce them in book-form. And in their new guise they form a volume which can scarcely fail to be acceptable to readers with limited purses, since, while every species is figured, the published price of the work is only five shillings. Neither can it be said that the volume is "cheap and nasty"; the type being clear and good, and the illustrations for the most part of high merit. Perhaps, indeed, they lack the pictorial elegance of photogravures, but as good specimens of wood-engraving they leave little to be desired; and there are many reasons why that style of illustration should not disappear from works of natural history. In many respects Mr. Duncan appears to be a disciple of Bewick; and in the case of the cuckoo (p. 142) so closely has he followed his master that his figure is merely a reversed replica of the original cut, with some additional details of surroundings. Generally, however, the figures are original, and they are often in advance of those of Bewick.

Although brief, the descriptions appear sufficient to identify the species. In the introduction, by Mr. C. Dixon, criticism of the work from a literary standpoint is deprecated; but the author might have ascertained that the British Isles form part of the Palaearctic region (p. 191), and also that the word *palaios* contains four vowels. As a whole, the volume is a highly creditable and artistic production. R. L.

Railway "Block" Signalling. By James Pigg, A.I.E.E. Pp. 387. (London: Biggs and Co.)

THIS account of the development and details of the "block" system of railway signalling brings together a large amount of interesting information upon a method of regulating railway traffic which has assisted very considerably in bringing about the present state of precision and safety in railway work. The system has been in use for about thirty years, and it now represents the most extensive of all the adaptations of electricity to railway work. Mr. Pigg describes clearly the principles of train signalling and the apparatus employed; he also includes in his work the codes, regulations, and rules relating to railway signals of various kinds. With regard to the lines along which developments will probably be made he remarks: "Railway signalling appears to have now reached a stage at which some departure from the present methods seems probable. The lines upon which changes will be made will, in all probability, result in a greater degree of automatic control than obtains at present."

The volume is an instructive contribution to an important subject.

The Story of Geographical Discovery. By Joseph Jacobs. Pp. vi + 224. (London: George Newnes, Ltd., 1899.)

MR. JACOBS has written a very readable little book. The historical aspect of geographical discovery is interestingly dealt with, and many subjects not usually included in books of geography are rightly given considerable prominence. The text is illustrated with twenty-four helpful maps, which serve to show the gradual increase of knowledge of our globe. The concluding table, showing the progress of geographical science from the time of Anaximander of Miletus down to the voyage of the *Challenger*, is most instructive. The author has collected his material with discrimination, and has evidently devoted much time and care to the preparation of his inspiring little volume. The recent marked development of imperial instincts should ensure the book the popularity it merits.

The Sphere of Science: a Study of the Nature and Method of Scientific Investigation. By F. S. Hoffman, Ph.D. Pp. viii + 268. (New York and London: G. P. Putnam's Sons, 1898.)

THIS book is the outcome of a series of lectures recently given by the author to his classes in Union College, to supplement their work in formal logic. Its object is to make clear what constitutes a science, and the grounds upon which every science must rest.

Very naturally, an important place is given to such considerations as the aims of science, what science takes for granted, the scientific method, and the limitations of science. Dr. Hoffman is always readable, and his style is pleasing. The book is by no means only a text-book; it will be found interesting by many educated readers, and should prove particularly useful in providing students of science with a knowledge of the groundwork of scientific investigation.

Chloroform: its Absolutely Safe Administration. By Robert Bell, M.D. Pp. 40. (Glasgow: R. L. Holmes, 1898.)

DR. BELL states the results of over thirty years' experience in the administration of chloroform. He writes "as one having authority," since he has no death to record from the use of chloroform throughout this long practice. It is maintained that when properly administered, there is absolutely no danger attending the use of chloroform as an anaesthetic; and Dr. Bell gives a large amount of evidence in support of his contention.

A Middle Algebra. By William Briggs, M.A., and G. H. Bryan, Sc.D., F.R.S. Pp. vi + 354. (London: W. B. Clive.)

IN this volume a knowledge of the more elementary properties of quadratic equations and progressions is assumed, and the requirements of candidates for the intermediate examinations for degrees at the University of London are especially borne in mind. Prof. Bryan's name is a guarantee for the accuracy of the book; and the arrangement, printing, and general appearance leave little to be desired.

Primer of Geometry. By James Sutherland, M.A. Pp. 117. (London: Longmans, Green, and Co., 1898.)

MANY of the early propositions in Euclid's First Book are reduced to actual measurements in this volume, and are thus brought within the ready grasp of the mind of the average boy. The book really teaches the rudiments of geometry and mensuration upon Fröbelian principles. Where the exercises it contains can be carried out, some of them will prove of educational value; but others are misleading.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Syrian Fishes with Abnormal Eyes.

NEAR the town of Hasbeya, Syria, arise springs which constitute in part the source of the small Hasbany river. In a short stream formed by those waters, I have found several varieties of abnormal-eyed fish, which, for convenience, may be grouped under five heads.

Fishes with (1) large protruding eyes; (2) an eye normal, and the other large and protruding; (3) half-protruding eyes; (4) two abnormal eyes unequal in size and development; (5) one eye normal, and the other rudimentary. At less than a hundred feet from the above-mentioned stream are two caves, but, strangely enough, only normal-eyed fishes could be found in the waters adjacent. The abnormal fishes are restricted to that stream, and are in the ratio of about one to four to the normal ones. The water is cold and tolerably clear, shallow near one bank and gradually deepening towards the other, to a depth not exceeding 7 feet in summer. No kingfishers or other fish-catchers were observed. Some of the fishes belonging to No. 1 had dark bodies and dark eyes, and seemed from their mode of motion to be little, if at all, sensible to light. Others belonging to No. 2 showed, by introducing a foreign object now near the normal eye and now near the abnormal one, that the latter saw less than the former. Dr. William van Dyck and Prof. A. E. Day, of the American College in Beirût, saw the fishes, and agreed that they had not met with any of the like during their study of the fauna of Syria. I may state that, having a small quantity of specimens, I would very willingly put it at the disposal of any specialist who may be interested in the question.

SALEEM MAKARIUS.

Al-Mokattam, Cairo, December 2.

Birds and Poisonous Fruit.

IT is naturally difficult to obtain direct evidence as to how birds rid themselves of the indigestible parts of the fruit they eat. It is a question to which I have given some attention from its bearing on the dispersal of seeds. I have found large quantities of the seeds of hawthorn, dog-rose, mistletoe, and ivy evidently voided by birds, as I incline to think generally as fæces, especially in the case of the hawthorn and ivy. Some large bird, I suppose the rook, consumes ivy berries largely in the spring, and gets rid of the seeds in what appears to be a mass of excrementitious matter. Many of these have not lost their vitality, and germinate readily in the same season. I have some thriving ivy plants obtained from such seed sown in 1896, and numerous seedlings this year of similar origin, the seed being sown on April 28, and coming up on June 7. I do not think much stress need be laid on the fact that much of the fruit swallowed is voided undigested, though the mistle-seeds I found were in a mass something like a lump of frog-spawn, with much of the pulp of the berry still adhering to each seed. I fancy birds and beasts, like many human beings, frequently swallow greedily far more than is good for them, especially when they light upon an abundant supply after enforced abstinence. An observant farmer informs me that horses coming in hungry to the manger will, if allowed, swallow corn more rapidly than they can digest it, if the grains are supplied whole, and that a large proportion passes in a condition to germinate. For this reason he has it crushed before given to them. I could supply Mr. Bennett or Mr. Lowe with some other curious evidence on this question if they care to have it, and will send their address.

Bedford. E. M. LANGLEY.

I CAN confirm Mr. Lowe's theory on this question.

For many years I have had robins coming to the hand for food in my garden. Before flying to the hand they constantly wait until they have succeeded in ejecting seeds from their crops. Great tits and blue tits also come to the hand, but never pause to eject anything. They are probably not large consumers of poisonous fruits.

I have on my lawn a large round china dish on an iron stand, in which many birds bathe, and from which they drink at all

hours of the day. I often see the bottom of this dish sprinkled with seeds, evidently ejected by the birds. At present they are the seeds of the Laurustinus (*Viburnum Tinus*).

Rosehill, Falmouth, November 29. Howard Fox.

Periodic Tides.

The letter of Mr. A. S. Thompson, in your issue of December 8, adds further interesting information as to secondary undulations, to that which I sent you in a paper printed in Nature of February 3 last. This paper appears to have escaped Mr. Thompson's attention, as in it he will find that this subject was investigated on the Swiss Lakes by Duillier in the middle of the last century, and by Vaucher in 1804. They found that these undulations are common to all lakes at intervals of about twenty minutes. More recently the subject was taken up by Mr. Napier Denison on the Great Lakes in Canada, where he found oscillations of three to four inches at intervals of from fourteen to eighteen minutes; and by Mr. Bell Dawson during the tidal survey of the Gulf of St. Lawrence, where he found regular minor undulations occurring, in addition to those due to the tides. W. H. Wheeler.

December 10.

Cristatella Mucedo.

As this very beautiful polyzoon is generally believed to be nearly, if not quite extinct in ponds in the neighbourhood of London, I should like to record the fact that on November 19 last, I took a fine specimen two inches in length, which is still living. The colony was packed with statoblasts, most of which are now discharged. It was not perfect when taken, and has again divided since it has been in a small aquarium.

Henry Scherren.

9 Cavendish Road, Harringay, N., December 3.

The Invention of the Gimbal.

Will you or some of your readers kindly inform me, when and by whom the construction of the gimbal was contrived for the first time? Kumagusu Minakata.

7 Effie Road, Walham Green, S.W.

THE VALUE OF EXERCISE.[1]

The value of exercise for the purpose of maintaining *mens sana in corpore sano* has been recognised from the remotest antiquity. Exercise, however, in its entirety seems to be divided into two sections which, though springing from the same cause, have led to different results: professional exercise or the training and maintaining of a body of athletes, and what may perhaps best receive the name of domestic exercise. The former appears to be one of the many instances of what was originally a means of becoming an end. Professional athletics doubtless took their origin in the use of exercise as a means; the perfect development of body and mind being the end. The huge muscles and small heads of professional athletes show us that the original means has finally become the end. This result from the point of view of the hygienist must be regarded as grotesque, and to the physician the professional athlete is neither more nor less interesting than the macrocephalic dwarf. The fainting and sickness of the over- or under-trained schoolboy, and the insomnia of the over-crammed student are essentially phenomena of the same class, and due to the same cause—viz. pathological plethora of some vascular areas, and pathological anæmia of others.

The use of exercise as a therapeutic agent, as also its use for the maintenance of health, falls under the second variety. The practice of exercises as part of one's toilette is very old. Any one conversant with the "heilgymnastik" (curative exercises) of the present day, let them belong to the systems of Ling, Schott, or Zander, cannot fail to be impressed with their resemblance to the devotional exercises of the devout Mahometan. Although doubtless the positions assumed by the worshipper are symbolical of passive submission, cringing obeisance, or subjected defiance, the point of interest to the physiologist is that after the performance of these devotions one experiences a distinct sense of fatigue. Thus by incorporating in his system of devotion actual muscular exercise the Prophet practically prescribed a system of "heilgymnastik," and forestalled the modern hygienic use of exercise. It would be interesting to know to what extent the exercise part of his devotions may be modified in the case of a Mohametan with *morbus cordis*. One fact, as will appear from the context, is worthy of notice. The devotional exercises are all performed slowly, and the change of posture is gradual. This is doubtless from a religious standpoint reverential, but from a physiological standpoint it prevents the occurrence of breathlessness or palpitation. In the one case which I had the opportunity of observing (devotion at sunset), the respirations were accelerated by four, the pulse by sixteen per minute by the devotions. This was in Algeria, near Hammam Rhira, at an altitude of 2000 feet. This effect might, no doubt, partially be due to psychical influences.

The modern therapeutic use of exercise is mainly directed to the attainment of two objects, local or general. The local use of exercises for the strengthening of certain groups of muscles mostly interests the surgeon or the neurologist. The ingenuity of Zander in inventing machines by which almost every group of muscles in the body can both be exercised, and made to do an exactly graduated amount of work, has done much to develope and systematise treatment in this branch of therapeutics. In the case of all muscles, including the heart, an optimal contraction is only obtained when the muscle contracts against an optimal resistance. This optimal resistance varies according to the condition of the muscle. In the case of the local use of exercise it is most important at the beginning of each set of exercises to find the optimal load. The great advantage of the mechanical system of resistance exercises, as compared with the manual method, is that once this optimal load is found it can be maintained constant, or as the condition of the muscle improves can be accurately increased. From this it follows that the work done on each occasion can be measured mathematically. It is impossible to achieve this by hand.

The second object aimed at by the therapeutic use of exercise is the one of most interest to the physician, viz. the production of a general systemic effect. This effect manifests itself chiefly upon the circulatory and respiratory systems. The sweating produced by exercise, although bringing into play the secretory function of the skin, and thus causing the excretion of certain noxious substances, as well as possibly the production and addition to the blood of an internal secretion, is essentially a circulatory phenomenon, and will not be further considered here, especially as exercise is, therapeutically, rarely pushed to such an extent as to produce sweating. One of the effects of exercise upon the respiratory system is known to every one, viz. breathlessness, or an increase in the depth and frequency of the respiratory movements. This dyspnœa varies according to the condition of the patient, and the amount or rather acuteness of the exercise. Physiologists are indebted to Zuntz and Geppert (*Pflüger's Archives*, xlii. p. 159) for having added most essentially to our knowledge of this condition. Before the work of these observers the dyspnœa attending exercise was held to be due to a diminution in the amount of oxygen and an increase in the amount of CO_2 in the blood; was, in short, regarded as an asphyxia. This hypothesis was based upon the experimental results of Mathieu and Urbain ("Du Gaz du Sang," *Archives de Phys.*, iv., 1871–72). Zuntz and Geppert, however, showed

[1] "Respiratory Exercise in the Treatment of Disease." By Harry Campbell, M.D., B.S., F.R.C.P. Pp. viii + 200. (London: Baillière, Tindall, and Cox, 1898.)

that during and immediately after exercise the amount of O in the blood was increased, and amount of CO_2 diminished as compared with their amounts at rest. They further concluded that during muscular exercise the contracting muscle poured into the blood substances the chemical nature of which was unknown, but which exerted a stimulating action on the medullary repiratory centre. In this phenomenon, according to them, neither pulmonary nor muscular centripetal nerves play any *rôle*. This latter dictum has been disputed by Filehne and Kionka (*Pfluger's Archives*, lxii. 96, p. 201), who hypothecate the existence of afferent nerves in the lung and muscles, which are sensitive to CO_2 production and are stimulated thereby. The main result of Zuntz and Geppert's work was not challenged by them, and still stands. In a later monograph Zuntz and Geppert maintain, and apparently correctly, their former work in its entirety.

This increased respiratory activity is within certain limits from a therapeutic standpoint a desideratum, as pulmonary resistance is thereby diminished, and the general circulation and flow of lymph accelerated.

In order to produce this salutary effect the respiration during exercise should be easy and full, and anything approaching effort, with its usual concomitant, closure of the glottis, should be avoided.

In this connection Dr. Campbell's recent book is interesting and useful. We cannot agree with the view expressed on p. 111, with regard to the causation of the dyspnœa attending exercise. The author at the close of his book gives a list of respiratory exercises calculated to attain certain ends. Dr. Campbell has produced an instructive and interesting monograph, and we shall be pleased to welcome his promised work on the mechanical treatment of heart disease.

Concerning the effect of muscular exercise upon the circulatory system, we have a very abundant literature to review, both physiological and medical. The recent development which this branch of therapeutics has taken, as exemplified by the thousands of visitors flocking to Nauheim, and the various mechanic, or manual gymnastic institutes, and the still larger numbers treated at their own homes, render the subject of considerable interest. The effects of the contraction of a muscle or group of muscles upon the circulation may be divided into local and general. The local effects, or the effect of its contraction upon the circulation through a muscle, was first investigated by Ludwig and his pupils, Sczelkow, Sadler and Gaskell. Some of Sadler's (*Ludwig's Arbeiten*, 1869, p. 77) results have a direct bearing upon resistance exercises as practised at the present day, since he studied the circulation through a group of muscles which were thrown into contraction, but were at the same time prevented from becoming shortened. He found that, as in the case of muscles contracting under ordinary circumstances, more blood passed through them than in the condition of rest. He also found that more blood passed through the contracting muscles when they were prevented from becoming shortened. than when they were allowed to do so.

Gaskell's (*Ludwig's Arbeiten*, 1877, p. 45) experiments showed that the maximum flow occurred either at the end of a long contraction (tetanus), or directly after the cessation of a contraction. In all these experiments the excitant was electric stimulation. In the case of exercise in the living animal the excitant is either volitional or reflex. The results, however, of Cheauveau and Kaufmann (*Archives de Phys.*, 1892, p. 279), who worked on the masseter of the horse during mastication, and in the main confirmed the above results, showed that the artificial nature of the excitant in Ludwig's experiments made no appreciable difference. Mosso[1] found that the volume of an arm as measured phlethysmographically increased immediately after contraction of the flexors. Some experiments I made conjointly with Dr. Lauder Brunton[1] showed that the amplitude of the pulsation of the arteries contained in the gastrocnemius increased considerably immediately after contraction of this muscle. The tracing showed that in addition to the arteries being dilated immediately after contraction they were relatively fuller of blood.

These results, obtained by different methods and by several observers, seem clearly to indicate that one of the local circulatory effects of muscular exercise is a dilatation of the vessels of the corresponding muscular area; or, in other words, a lessening of the resistance to the flow of blood through the muscles. In view of the relaxation of the antagonistic muscles which apparently accompanies the contraction of any group of muscles, it would be interesting to see what, if any, changes occur in the vessels of these relaxing muscles. If a dilatation occurs here also, as seems *à priori* probable, the vascular area affected would be considerably increased, and then the effect on the general circulation would be magnified.

If we turn from the local circulatory effects of muscular contraction to the effects produced on the general circulation by the contraction of a group of muscles, we shall find in the first place that a determining factor of the greatest importance is the amount of exercise; and this is best measured by the degree to which the respiration is affected. The results of former observers, Marey ("La Circulation du Sang," 1881, 343). Oertel,[2] von Basch, and others, have been entirely confirmed by those of more recent investigators, viz. Hallion and Comte (*C. R. Soc. de Biologie*, x. serie, iii. 906), Bloch, Mosso (Der Mensch auf den Hochalpen Leipsig, 1899), Brunton and myself (*loc. cit.*), Zuntz and Hagemann (*Deutsch Med. Woch*, 1892), Taugl and Zuntz (*Pfluger's Archiv.*, lxx. 544, 1898), and Kaufmann (*Archives de Phys.*, serie 5, t. iv. p. 493). Zuntz and his collaborators are evidently unaware of the work of Mosso and his pupils, and of Brunton's and my own paper.

The results of Zuntz and his collaborators showed that in the horse a gentle walk was accompanied by a fall in blood pressure amounting to about one-twelfth. In the case of dogs, gentle exercise was accompanied by a slight rise in blood pressure amounting to one-twelfth or one-tenth, whereas violent exercise rapidly caused a doubling of the blood pressure in the carotid. The experiments made in Mosso's laboratory on man, including those contained in Brunton's and my own paper, confirm the above results obtained upon animals. However gentle the exercise, an increase, sometimes very slight in blood pressure, occurs; this, however, sometimes during exercise, invariably after it, is followed by a fall, which continues for some time after the exercise has ceased. If the exercise is violent the accompanying rise in blood pressure is considerable one-sixth to one-eighth, and this high pressure is continued so long as the exercise lasts, the pressure gradually returning to its former level; this, in some cases, taking two hours or more. All observations upon the blood pressure in man directly after exercise more or less severe, which have been sufficiently numerous, confirm these results (see "Oertel," *loc. cit.*). These experiments are of interest from a therapeutic standpoint, in that they show that it is possible to obtain the beneficial effects of exercise at the expense of a very slight extra strain upon the heart.

A question at the present time of considerable interest is, how are the cardio-vascular results which follow exercise brought about? Are we to assume that they are central, and are produced by the action of substances of

[1] "Sulle Variazioni locali del polso nel ante-braccio del uomo." Torino, 1878.

[1] "Remarks on the effect of Resistance Exercises in Man, local and general." (*British Medical Journal*, October 16, 1897.)

[2] "Handbuch der allgemeiner Therapie der Kreislaufs Storungen." Leipzig, 1891.

unknown chemical nature, the products of muscular contraction, acting upon the medullary centres, or that they are reflex? In this latter case two hypotheses may be adopted—viz. that the afferent impulse is due to peripheral chemical, or peripheral mechanical stimulation. So far as I am aware no work has been done on the lines of Geppert and Zuntz (*loc. cit.*), or Filehne and Kionka (*Pfluger's Archives*, Bd. lxii, 201, 1896) with regard to the vascular effects of exercise. A paralysing action on motor nerve endings has been ascribed to the products of muscular activity, but to what extent the nerve endings in non-striped muscle are influenced by these products has not been shown. A further question of interest, which remains yet to be decided, is what are the vascular areas which become anæmic during exercise? The nausea or vomiting, which is the frequent accompaniment of violent exercise when one is in "bad condition," seems to point to the splanchnic area as the one at the expense of which the muscular plethora occurs; but, so far as I am aware, no phlethysmographic records of the abdominal organs during extensive muscular contraction have as yet been made.

In considering the effect of the contraction of a muscle upon the circulation through it, the muscular substance of the heart itself naturally comes into consideration. The circulation through the coronary arteries when these vessels have not lost their normal elasticity from atheroma or other causes, is unquestionably increased by full and frequent cardiac contraction, and the state of nutrition of the heart thereby improved. Further, increased pressure in the aorta within certain limits is advantageous to the coronary circulation. The experiments which have been made recently upon the excised mammalian heart (Langendorf, *Pfluger's Archives*, lxx., 1898, p. 473) tend to show that the conditions for optimal contraction—that is, for a maximum output of energy at each beat—are practically the same in the case of the mammalian as in that of the frog's heart (Tunnicliffe, *Journal of Phys.*, xx. 1, 96). Of these one of the most important is the choice of an optimal load, the cardiac muscle in this respect being similar to ordinary striped muscle. This, from a practical standpoint, amounts to the fact that although a heart can be, and of course very often is overloaded, or in other words is unable to meet the resistance which the normal circulation offers to its contraction, it can also be underloaded; that is, the cause of its insufficient contraction may be that not sufficient resistance is offered to its systole. This underloading of the heart may play an important *rôle* in sluggish circulations in women, and men living sedentary lives. Fairly severe but gradually commenced and gradually increased exercise in these individuals will often supply the necessary load, and bring back the cardiac action to the normal. It is the function of the physician to discriminate between the over- and under-loaded heart, and to treat it accordingly; exercise may find a place in each variety of this treatment.

In this paper nothing has been said with regard to another aspect of exercise from a therapeutic standpoint. We have discussed the possibility of certain chemical substances produced during the contraction of muscle exerting an action on the respiratory and cardio-vascular centres, but we have said nothing of the possible effect on general metabolism of such products or others accompanying them. That such an effect is produced is seen by the general nutritive results of local muscular exercise and of massage. Whether the physiological basis of such a result consists in the removal of waste products—that is, is essentially increased excretion—or in the production of substances which have an action allied to the internal secretion of glands, remains yet to be decided.

F. W. TUNNICLIFFE.

THE ZOOLOGICAL EXPLORATION OF THE GREAT AFRICAN LAKES.

OWING to the unique and extremely interesting nature of the fauna in Lake Tanganyika, the study of which was recently the object of an expedition supported by the Royal Society, and led by Mr. J. E. S. Moore, a Committee has been formed, consisting of Sir John Kirk, G.C.M.G., K.C.B., F.R.S. (late British Resident at Zanzibar), Dr. P. L. Sclater, F.R.S. (secretary to the Zoological Society), Mr. Thiselton-Dyer, C.M.G., F.R.S. (director of Kew Gardens), Prof. Ray Lankester, F.R.S. (director of the Natural History Departments of the British Museum), and Mr. G. A. Boulenger, F.R.S. (of the British Museum), for the purpose of organising another expedition to the same regions, to thoroughly survey the basin, not only of Lake Tanganyika, but also the unknown portions of the northern extension of the great series of valleys in which Tanganyika, together with Lakes Kivu and the Albert Nyanza, lie; to collect specimens of the aquatic fauna and flora, and to study the geological history of this part of Africa. The latter object of the investigation should be of especial interest, for it was shown by Mr. Moore that almost without exception the shells of the singular series of whelk-like molluscs, captured by him in Tanganyika, are indistinguishable from those now found fossilised in Europe, among the remains of old Jurassic seas. It would thus appear that at some remote period of time, the great valley of Tanganyika was in connection with the sea, and that the strangely isolated marine fauna, which still inhabits its slightly brackish waters, has remained there ever since. So far only the *Medusae* (jelly-fish), the *Mollusca*, and the *Crustacea*, belonging to this antique fauna, have been discovered in the lake; but when its vast size and depth are fully realised, it is unquestionable that by far the larger portion of its fauna is as yet unknown.

Tanganyika thus presents a unique field for scientific exploration at the present time, and is, indeed, one of the few places now left upon the earth where animals (like those peculiar to Australia) which have long since become extinct elsewhere, may still be found.

Another notable fact ascertained during Mr. Moore's last expedition, was that the marine, or *Halolimnic* fauna of Lake Tanganyika does not exist in either Nyassa or in Lakes Shirwa, Mwero, Bangweolo, or any of the remaining lakes about which anything zoological is known; but it may yet be found in Lakes Kivu, the Albert Edward and Albert Nyanzas, which lie, as has been said, in an extension of the same great depression which contains the Dead Sea towards the north. The probability of this being so, is also increased by the curious fact that the fauna of Tanganyika bears some resemblance to that of the lower portions of the Nile.

During the present expedition it is therefore intended to go north from Tanganyika, which will form the zoological headquarters of the expedition, through the unknown region which lies between Tanganyika and Lake Kivu, on, finally, to the Albert Edward and Rowenzori districts. It is intended then that the expedition shall pass eastward, through the Uganda stations north of the Victoria Nyanza, down the Uganda roads and railway to the sea. Mr. Moore's previous expedition was hampered by the unexpected difficulties of transport and the want of a steamer properly to carry on dredging and sounding operations in the lake, and, in consequence of this, much valuable material, particularly large specimens of entirely new species of fish, had to be deliberately left behind. At the present time, however, the African Lakes Corporation are running the London Missionary Society's old steamer once more upon the lake, and all these deficiencies can therefore now be overcome, provided the necessary funds are raised.

A careful consideration of the details of the expenditure has led the Committee to the conclusion that in order to enable Mr. Moore to successfully lead another expedition for two seasons, and to accomplish the above-stated objects, a sum of not less than 5000*l.* wtll be required. The Committee have already received encouraging offers of support, including one of 1000*l.* from a gentleman connected with the commercial and political interests of British Africa. They point out, however, that the results to be obtained will increase almost in the ratio of the square of the initial expenditure; and in a private circular, which has been issued, the members of the Committee appeal to those who feel interest in the objects of the expedition, for assistance in carrying out an enterprise which is not only of the highest scientific importance, but is also of great significance in securing British influence in a critical region of the African interior.

UNIVERSITY COLLEGE AND THE UNIVERSITY OF LONDON.

We are glad to be able to publish the following text of a resolution adopted by the Council of University College, London, at their session on December 10. The offer contained in the resolution is a noble one; and we hope that the example afforded by it will be followed by other similar institutions, in order that the labour of the Statutory Commission may be simplified.

That a Deputation be appointed to represent to the Statutory Commission that—inasmuch as

(1) University College, London, was founded as the University of London, with the object of providing a complete University education in London of the highest type.

(2) The intention of the founders and benefactors of University College will only be carried out by the incorporation of the College in the University, so that its resources shall still be utilised for the furtherance of the highest educational work and for research.

The Council are prepared to summon a general meeting of the members of the College, and to propose to them that such steps should be taken as may be necessaiy for placing the site, land, buildings and endowments of the College at the complete disposal of the reconstituted University.

In making this offer the Council do not desire to throw any obstacle in the way of any other institutions in London which may be disposed to place their resources at the disposal of the Governing Body of the University.

It will be necessary in accordance with the precedent afforded by the Universities Act (Oxford and Cambridge) to protect the interests of the existing teachers and executive staff of the College. The existing teachers are, however, to have no claim as such to any rank in the re-constituted University, or to any vested interest other than that they now have in the College.

Special provision will probably have to be made as to the boys' school and its endowments, and perhaps for appropriate buildings on another site being provided for this department of the College work. Arrangements will also have to be made with regard to the Hospital and its funds, of which the College is now the Trustee.

(Signed on behalf of the Council),
J. Gregory Foster,
Acting-Secretary.

NOTES.

Prof. Marsh has been elected a correspondant of the Section of Mineralogy of the Paris Academy of Sciences, in succession to the late Prof. James Hall.

The Geographical Society of Berlin (Gesellschaft für Erdkunde zu Berlin) have sent out a circular inviting the friends and promoters of geography in all countries, and especially the members of geographical societies and cognate scientific bodies, to be present at the seventh International Geographical Congress, to be held in the German capital from Thursday, September 28, to Wednesday, October 4, 1899. Before the beginning and after the close of the Congress, excursions will be arranged through such parts of Germany as are of interest from the points of view of physical or economic geography. The subjects which are to be discussed at the Congress will be arranged in the following groups: (1) mathematical geography, geodesy, cartography, geophysics; (2) physical geography (geomorphology, oceanology, climatology); (3) biological geography; (4) industrial and commercial geography; (5) ethnology; (6) topical geography, exploring travels; (7) history of geography and of cartography; (8) methodology, school geography, bibliography, orthography of geographical names. According to the usual custom, the English, French, German, and Italian languages will be admitted as languages of the Congress, and all papers must be written in one of them. The latest date for receiving papers is June 1, 1899; and the subjects should be notified by April 1, 1899. All correspondence relating to the Congress should be addressed to the VII. International Geographical Congress, 90 Zimmerstrasse, Berlin, S.W.

Dr. Capitan has been elected president of the Paris Anthropological Society for 1899.

The Desmazières prize has been awarded by the Paris Academy of Sciences to Dr. J. B. de Toni for his "Sylloge Algarum."

The Paris correspondent of the *Chemist and Druggist* states that a "Retrospective Museum of the History of Chemistry" is being organised to figure in the Paris Exhibition of 1900. It will comprise objects relative to scientific discoveries and industrial improvements—in fact, everything that can clearly show the successive progress accomplished in the chemical industry and the importance of the discoveries made by French savants. Amongst the objects indicated as admissible are laboratory apparatus, reports on discoveries, portraits of inventors, investigators, and manufacturers, descriptions of processes, products obtained by inventors or in scientific laboratories, drawings, plans, models in relief, &c. Industrial museums, faculties, schools, manufacturers, and private individuals are invited to send a list of articles they may be willing to lend.

A prize of 1000 marks is offered by the Economic Society of Mohrungen, near Königsberg, for the best work on the relations of electricity to living organisms. The work must discuss either fundamentally new phenomena in plant or animal electricity, or, from the point of view of physics, discuss the sources of organic electricity, or its significance for life in general or for certain functions.

Very little is at present known of the flora of Porto Rico. This is not likely to remain long the case, since the attention of the Americans has been turned to the island. An American citizen, Mr. Cornelius Vanderbilt, has offered to bear the expense of a botanical expedition to the island by Mr. A. A. Heller, under the auspices of the New York Botanical Garden

An informal Committee will shortly meet in Calcutta to consider the reports by the Astronomer Royal and Sir Norman Lockyer, who were recently asked for advice regarding Indian astronomical and solar observatories. The future working of these observatories will be discussed, and Sir James Westland, Messrs. T. Holderness and J. Eliot, and General Strahan, Surveyor-General, will probably be members of the Committee.

It is announced that the Royal Academy of Medicine of Belgium has appointed a Commission to consider the following proposal:—"The Royal Academy of Medicine asks the Government to enter into negotiations with foreign Governments with a view to drawing up an International Pharmacopoeia."

A SHORT course of lectures adapted for a juvenile audience will be given at the Society of Arts on Wednesday evenings, January 4 and 11, 1899, at 7 o'clock, by Prof. F. Jeffrey Bell. The first lecture will be on "Hands and Feet," and the second lecture on "Some Ways in which Animals Breathe."

THE following are among the Lecture Arrangements at the Royal Institution before Easter:—Sir Robert Ball, six lectures (adapted to young people) on astronomy; Prof. E. Ray Lankester, ten lectures on the morphology of the mollusca; Mr. A. Henry Savage Landor, three lectures on Tibet and the Tibetans; Dr. Allan Macfadyen, four lectures on toxins and antitoxins; the Right Hon. Lord Rayleigh, seven lectures on the mechanical properties of bodies. The Friday Evening Meetings will begin on January 20, when a discourse will be delivered by Prof. Dewar on liquid hydrogen; succeeding discourses will probably be given by the Right Hon. Sir Mountstuart E. Grant Duff, Mr. Victor Horsley, Prof. H. S. Hele-Shaw, Mr. Richard R. Holmes, Sir Frederick Pollock, Bart., Prof. H. L. Callendar, the Right Hon. Lord Rayleigh, and other gentlemen. The year 1899 is the centenary year of the Royal Institution, and arrangements are being made with a view to its celebration in a fitting manner. Details will be announced at a later period.

REFERRING to next year's meeting of the British and French Associations, the Paris correspondent of the *Times* remarks:—Science, happily, has no politics, and the French Association for the Advancement of Science, with the view of fraternising with the British Association, has fixed its next congress for September 14 to 22 at Boulogne. The office-bearers of the two associations have agreed on a joint gathering at Dover during the two congresses. Although the younger association will thus cross the Channel to show its deference for seniority, it is understood that there will be a return visit. The French Association having thus, so to speak, broken the ice, it may be hoped that, just as it has already held a congress across the Spanish frontier, it will before long receive and accept an invitation from some English town. The distance can evidently be no objection, for it has held two congresses in Algeria and a third in Tunis.

SIR WILLIAM JENNER, G.C.B., F.R.S., Physician in Ordinary to the Queen and to the Prince of Wales, died on Sunday, at the age of eighty-three years. From a long obituary notice in the *Times*, we extract the following particulars of his career:—He was born in 1815, at Chatham, and was educated at University College. In 1844 he graduated as M.D. in the University of London; and in 1848 he was appointed professor of pathological anatomy to University College and assistant-physician to University College Hospital. In 1852 he was elected a Fellow of the Royal College of Physicians, and was appointed Gulstonian Lecturer. He then became physician to the Hospital for Sick Children, assistant-physician to the London Fever Hospital in 1853, and full physician to University College Hospital in 1854. In 1857 he succeeded to the professorship of clinical medicine in University College. In 1862 he was appointed Physician in Ordinary to Her Majesty, and professor of the principles and practice of medicine at University College. In the following year he was appointed Physician in Ordinary to the Prince of Wales, and in 1864 was elected a Fellow of the Royal Society. He was created a baronet in 1868, K.C.B. in January 1872, and G.C.B. in 1889. He was President of the Royal College of Physicians from 1881 to 1888, and had received honours from many learned bodies both in this country and abroad. He was a D.C.L. of Oxford, LL.D. of Cambridge and of Edinburgh, a Commander of the Order of Leopold of Belgium, and an honorary member of the Belgian Academy of Medicine. Jenner was not a voluminous writer. His chief works were on the "Identity or non-identity of typhus and typhoid fevers," and on "Diseases commonly confounded under the term continued fevers." He also published his Gulstonian Lectures on emphysema, and two or three volumes of clinical lectures on diphtheria, rickets, tuberculosis, and other subjects.

AFTER a long illness, Sir William Anderson, K.C.B., F.R.S., Director-General of Royal Ordnance Factories, died on Sunday last, December 11. He was born in St. Petersburg in 1835, and was educated at the High Commercial School there, where he was head of the school and silver medallist, and had conferred on him the Freedom of St. Petersburg. He was a pupil of Sir William Fairbairn, and a member of the firm of Messrs. Courtney and Stephens, engineers, of Dublin, from 1855 to 1864. He communicated a number of papers on engineering subjects to the Institute of Civil Engineers of Ireland, and was President of that Society in 1863. He received the Telford medal and the James Watt medal of the Institute of Civil Engineers. He was distinguished for the ability with which he applied his knowledge of the science of heat, and other cognate sciences, to the practical requirements of the engineer. The knowledge of Russian obtained in early life enabled him to translate the works of Chernoff on steel, and the researches of General Kalakontsky on the internal stresses in cast-iron and steel. He was elected a Fellow of the Royal Society in 1891; and was Vice-President of the Institution of Civil Engineers, a Past-President of the Institution of Mechanical Engineers, and hon. D.C.L. of Durham University. In 1889 he was appointed Director-General of the Royal Ordnance Factories, and last year he was created a K.C.B.

A MEMORIAL has been prepared for presentation to the Lord President of the Council (the Duke of Devonshire) and the President of the Board of Trade (Mr. Ritchie), protesting against the proposed removal and distribution of the collection of fish which was brought together by the late Mr. Frank Buckland, and has formed the Buckland Fish Museum in South Kensington Museum. With the view of rescuing the museum and increasing its usefulness, it is proposed that it should be made part of the duties of the inspectors of fisheries to preserve and deposit in the Museum of Economic Fish Culture any objects of permanent interest which may come under their notice, together with models of improvements in fish passes, fish culture apparatus, &c., which may be useful for reference or record. It is also suggested that the secretary and the inspectors of the Fisheries Department, together with the representatives of the Fishmongers' Company, should be appointed visitors to advise on and aid in the efficient management and development of the museum.

THE death of Dr. James I. Peck, assistant professor of biology in Williams College, and distinguished for his investigations in marine biology, is announced in *Science*. The following particulars are given, by Prof. H. C. Bumpas, of his contributions to biological knowledge:—In 1888 Dr. Peck prepared one of the first serious contributions to the study of variation that had been made since the time of Darwin. The summer of 1889 he spent at Woods Holl, where he worked upon the habits of the young of certain food fishes. In 1890 he published his Cymbuliopsis paper. In 1892 he was again a member of the scientific staff of the Fish Commission Laboratory, where he worked upon the Pteropods and Heteropods collected by the *Albatross*. The summer of 1893 was spent in preparing his paper on the "Food of the Menhaden," and in 1894 he continued his plankton studies and prepared a paper on the "Sources of Marine Food." In 1895 he was placed in charge

the Laboratory of the Fish Commission, and in 1896 he ;cepted the position of assistant director of the Marine iological Laboratory.

THE *Chemist and Druggist* announces the death, at Grasse, M. Jacques Passy, who attracted attention some time ago by 's interesting researches on the chemistry of perfumes as gards their composition and physiological action. He was a iemist of promise, and one of the leading assistants of M. lfred Binet, the director of the laboratory of psychological iysiology at the Paris Sorbonne.

M. DE FONVIELLE writes :—"The success achieved on the ght of November 13-14 by the astronomer Hansky in his balon ascent, has induced M. Janssen to undertake further aerial :periments next year for the same purpose. At least two cents are to take place from three different stations; one in urope, one in America, and the last in Central Siberia. hese ascents are to take place respectively and successively—ree on the night of the 13-14, three on the night of the |-15, at 2 o'clock a.m., local time, and to last to 7 o'clock. he aeronauts will be instructed to re-ascend on the following orning, viz. 14 15 for the first, and 15-16 for the second. he balloons are to measure from 50,000 to 60,000 cubic et each in order to carry three men, one aeronaut and vo observers, supplied with electric lamps, celestial maps, ıd chronometers. The balloon is to ascend to an altitude 10,000 feet with registering thermo-baric hygrometer. Free lloons are to be sent up for testing the high atmosphere at an titude of 10,000 feet."

A FINE series of stereoscopic diagrams of the catenaries on a ıtating sphere, a paraboloid and a cone, as well as of geodesic ırves on oblate and prolate spheroids, accompanies Prof. A. G. reenhill's paper in the *Proceedings* of the London Matheatical Society, xxix. pp. 585-670, on "The Catenary and e Associated Trajectory on the Paraboloid and Cone." In e paper itself, the equations and properties of the curves presented are worked out by means of elliptic functions, and e understand that the illustrations are due in great part to ıe co-operation of Mr. T. I. Dewar. In order to make the ırves stand out in better relief, they are mostly drawn on a ıckground ruled to resemble a tesselated pavement.

THE thermodynamics of equilibrium in systems of two and ıree components having one liquid phase, forms the subject of ı interesting paper by Dr. Giuseppe Bruni in the *Atti dei incei* for October (vii. 8), in which the author derives the ıllowing conclusion :—If to a system of two components with nly one possible liquid phase there be added a third comonent which does not combine with the first two and is not omorphous with them, the curves expressing equilibrium of ıe same order (curves of saturation in binary systems and yohydratic curves in ternary systems) are parallel. Only in stems represented by the curve of the ternary mixture, the ıird added component exists mostly in the solid phase.

SINCE Lord Kelvin published in 1856 the details of the ıenomenon known as the Thomson effect, few experimenters ıve turned their attention to experiments of a quantitative ıaracter, Batelli's investigations being almost the only excepon. An absolute measurement of the Thomson effect in ıpper is described by Mr. R. O. King in the *Proceedings* of ıe American Academy of Arts and Sciences (xxxiii. 19). As atelli did not experiment with copper, no direct comparison ith his results can be made, but his value obtained for iron is ıout twice as great as Mr. King's present value for copper. ccording to Tait's assumption the value should be about five nes as great.

ATTENTION seems to have first been called to the errors in localising sounds by E. Weber. The particular problems involved seem to be two, namely, the perception of the direction from which a sound comes and the perception of its distance. An attempt to contribute data towards the solution of these two problems has been made by Matataro Matsumoto, of the Tokyo Imperial University, and his researches on acoustic space appear in vol. v. of the *Studies* from the Yale Psychological Laboratory. The author considers that an acoustic sensation receives its spatial form primarily from the space-idea which is given to us by the visual, tactile and motor sensations. Acoustic space presupposes the existence of the space-form of other sensations. We have only to give an account of how the perception of the position of sounds arises on the basis of the already existing space which was given to us by other senses; as to the further problem of the ultimate origin of the space-form of perception, its solution must be sought in the visual and tactile perception.

THE late Mr. W. J. C. Miller, formerly Registrar of the General Medical Council, was perhaps best known in his capacity of mathematical editor of the *Educational Times*. But he also devoted many of his leisure moments to writing popular articles on natural history, many of which he contributed to the Selborne Society's *Nature Notes* and other journals. These papers are now to be published in a volume entitled "Nature Studies," under the editorship of Mr. H. Kirke Swann. The book should prove very agreeable reading, besides providing, for the many friends of Mr. Miller, a lasting memorial of the author.

A CONVENIENT method of preparing filamentous algae and fungi for the microscope is described by Mr. Charles J. Chamberlain in the *Journal of Applied Microscopy*. Mr. Chamberlain uses Flemming's weaker solution or chromo-acetic acid for fixing, followed by iron alum hæmatoxylin for staining, and mounts in glycerin concentrated by gradual evaporation from a ten per cent. solution. It would be interesting to learn, in applying the method to desmids, whether these can be prevented from their not unfrequently persistent tendency of floating to the surface and getting carried off in the repeated washings that are necessary.

DR. BRINTON has reissued a short article, contributed to the *American Anthropologist*, on "The Peoples of the Philippines." The two stocks which were found in possession of the islands at their discovery by Magallanes in 1521 were the small black Negritos, now reduced to about 10,000 persons, and the brown Malayan peoples, who are in the vast majority. As Dr. Brinton says: "The ethnic and historic relations of these two races offer some interesting problems in anthropology"; and it is not too much to hope, now that America has obtained the sovereignty of the islands, that these problems will be investigated and the results published for the benefit of science. It is painful to be reminded of the absolute neglect of these important matters by the British Government, who, with better opportunities than is possible in any other country, do less than is done by most of the European Governments; while the English student turns naturally with hope to the American Government. Dr. Brinton inclines to the theory, in which we think he is correct, that these two races of the Philippines are ethnographically distinct. The Negritos, so called, are extremely rude, owning no fixed habitations, not tilling the soil, making no pottery, and possessing no clothing except a girdle. Among their beliefs is that when one of their own people dies it is due to the black art of their Malayan foes, and they kill a Malayan if they can. This has given rise to a curious and significant relationship between the conquerors and conquered, which Dr. Brinton does not mention by the way; and we think there is a good field for observation here in a matter not always accessible to the inquirer, but which is, nevertheless, of the

greatest importance. Of course, Dr. Brinton's note is only a summary of the present knowledge, but it is welcome.

IN *Das Wetter* for November, Dr. W. Meinhardus, of Berlin, discusses a fall of ice or frozen rain which occurred over a large part of the central and eastern parts of Germany on October 20. This phenomenon, which is sometimes called glazed frost, is one of the most peculiar and rarest forms of precipitation, which covers all bodies upon which it falls with a more or less thick layer of ice. From the reports received at the Berlin Meteorological Office, it appears that the frozen rain occurred with extraordinary violence in several localities. At Potsdam, Dr. Süring calculated that a blade of grass bore eight hundred times its own weight of ice. The ice-coating lasted through the whole of the day, and only disappeared with the setting in of a warm westerly current on the following morning. The occurrence of glazed frost is usually explained by the rain falling upon bodies below the freezing point, but no frosty weather had preceded the fall in this case. The conditions that produced it appear to have been (1) a layer of air in the upper regions, with a temperature above the freezing point; (2) this upper layer must have been moist, and have had a tendency to move upwards, so that condensation and rain-formation occurred; and (3) below this layer there must have been another stratum with a temperature below the freezing point. This inversion of temperature conditions is borne out by observations received from several of the mountain stations.

A PAPER on the ventilation of tunnels and buildings was read at the Institution of Civil Engineers, on December 6, by Mr. Francis Fox. In regard to the first part of the subject, Mr. Fox enunciated the proposition that if the amount of carbon dioxide in the air of a railway tunnel did not exceed 20 parts in 10,000, then the ventilation might be deemed satisfactory. The case of the Metropolitan Railway tunnels, having been the result of recent investigation, was not mentioned otherwise than to recall the fact that the amount of carbon dioxide in the air had been shown to be as much as 86 parts per 10,000. The great Alpine tunnels were next referred to. In the case of that under Mont Cenis, 8½ miles long and 26 feet wide, the higher altitude of the middle of the tunnel above its entrances was inimical to good ventilation, and at times great difficulty was experienced in carrying on the traffic. The St. Gothard Tunnel, 9¼ miles in length and 26 feet wide, was nearly level from end to end and, until recently, natural ventilation only sufficed, but, owing to increase of the traffic and the use of briquette fuel, the Saccardo system had lately been introduced. This consisted in blowing into the mouth of the tunnel a large volume of air which, on the principle of the injector, caused an induced current in the annular space between the interior surface of the tunnel and the gauge of maximum construction. In the second part of the paper Mr. Fox referred to the statement by Dr. Ransome, F.R.S., that 70,000 deaths occurred annually in Great Britain from tuberculous disease, nearly all of which could be saved were the subject of fresh air both understood and acted upon by the community. Competent medical authority considered that the quantity of carbon dioxide in the air of rooms should not exceed 10 parts per 10,000, equivalent to about 16 cubic feet per head per minute. In French hospitals 50 cubic feet per patient per minute was allowed. Mr. Fox considered that 20 cubic feet per minute would be sufficient for ordinary purposes. Tables were given of the impurity in the air of schools, with different systems of ventilation, of that in dwelling-houses, and of that in sewers; from which it appeared that the latter was the least impure of the three.

PROF. W. F. GANONG, of Smith College, Northampton, Mass., U.S.A., is desirous of obtaining accurately determined seeds of Cactaceæ for studies on the embryology of the order. His investigations on this subject are being published in th *Botanical Gazette*.

DR. N. WILLE has been appointed curator of the Museum and Herbarium of the University of Christiania, in succession t the late Prof. Blytt; and Dr. Carl Fritsch has been elected t succeed Kerner v. Marilaun as director of the Botanica Museum at Vienna.

LORD LISTER'S recent remarks upon the humanity of vivi section, reported in NATURE of October 20, have induced th Hon. Stephen Coleridge to gather a few extracts from th medical journals and the *Journal of Physiology*, and presen them as evidence of "prolonged and terrible tortures." Thi he does in the hope that Lord Lister will "*do himself* the justic to confess that his statement at Liverpool was inaccurate"!

THE English equivalent of the German word "Anlage" i still a matter of discussion among biologists. Among the word favoured by various writers are forecast, fundament, rudiment beginning, origin, and foundation. Dr. Arthur Willey recentl suggested in these columns (August 25, p. 390) the word prim ordium as an accurate and well-sounding rendering of Anlage Prof. Burt G. Wilder expresses a favourable opinion upon thi word in *Science*, but thinks the shorter word proton, alread familiar in numerous compounds, and used by many biologists is a better equivalent.

DR. AMICO BIGNAMI, lecturer in the Institute of Patho logical Anatomy of the Royal University of Rome, discusses i the *Lancet* the inoculation theory of malarial infection, an gives an account of a successful experiment with mosquitoes He remarks at the end of this week's contribution: "To sum up, malaria is a disease which is contracted by inoculation—a fact of which we have now obtained the first experimenta proof, since we have seen that an individual who has never ha malarial fever by sleeping in a healthy place where no one ha ever previously taken fever may sicken with malaria of a grav type if bitten by certain species of the mosquito brought in th adult state from some distant locality of highly malariou character. Further, everything points to the conclusion tha inoculation is the only mode by which infection is acquired since air and water as carriers of infection may be excluded and because arguments based on analogy all tend in the sam direction. This much at any rate we can assert—namely, tha inoculation is the only mechanism of infection which has bee demonstrated experimentally."

AN elaborate illustrated catalogue of apparatus used i physical and chemical laboratories and lecture rooms, an for bacteriological and microscopical work, has been issued b Messrs. W. and J. George, Ltd., the successors of the firm o Messrs. F. E. Becker and Co. The catalogue runs into no les than 662 pages, is printed on good paper, and profusely illus trated with pictures (many of them new) of instruments an accessories. Special attention appears to have been give to the arrangement of the contents, the description and pric of each piece of apparatus being immediately adjacent to th illustration of the apparatus. The overcrowded appearance o many catalogues of scientific apparatus is thus avoided, and all particulars with regard to any instrument are readily found The catalogue should be seen by teachers and investigators o all branches of experimental science.

IN a recent number of the *Journal für praktische Chemie* is an interesting contribution by Prof. Curtius and Dr. Rissom to the chemistry of azoimide and its metallic derivatives. Some losses having been noticed during the preparation of azoimide, by distilling a metallic salt with acid, it was found that heating

in contact with dilute mineral acids caused notable decomposition of the hydrazoic acid. A large number of metallic salts were prepared and analysed, and in every case the salts were found to be anhydrous. The metallic derivatives differ considerably in their explosive properties. Thus, of the derivatives containing the metals of the alkalis and alkaline earths (with thallium), lithium nitride is the only one exploding violently on heating, and thallium nitride the only one detonating when struck on an anvil. The action of heat upon the nitrides of these two groups is very remarkable, as when small quantities of the nitride are heated carefully in thin glass tubes, decomposition takes place quietly, nitrogen being evolved, and the pure metal left behind; this being, as the authors point out, much the easiest method of preparing small quantities of barium, strontium, and calcium.

THE additions to the Zoological Society's Gardens during the past week include an Egyptian Jerboa (*Dipus aegyptius*) from North Africa, presented by Miss Da Costa; an African Buzzard (*Buteo desertorum*), an Iceland Falcon (*Hierofalco islandus*), captured in the Red Sea, presented by Captain E. W. Burnett; a Peregrine Falcon (*Falco peregrinus*), captured in the Red Sea, presented by Captain Bear; a Rough-keeled Snake (*Dasypeltis scabra*) from South Africa, presented by Mr. H. Oakley; two Scops Owls (*Scops giu*), South European, deposited; a Brazilian Tapir (*Tapirus americanus*, ♀) from the Upper Amazons, two Common Rattlesnakes (*Crotalus durissus*) from North America, purchased; an Axis Deer (*Cervus axis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE GEMINIDS.—For the greater part of the evenings of the 10th, 11th and 12th of this month, clouds prevented observations of the Geminids in London. Late on the night of the 12th, however, when the sky became to some extent clear, a brief watch of an hour, from 11h. 30m. p.m. to 12h. 30m. a.m. G.M.T., disclosed the fact that these meteors were very much *en evidence*. Between 11h. 30m. and 12h. 5m. no less than twenty-four Geminids were observed, four of which were of great brilliancy and brighter than a first magnitude star. The direction of observation was necessarily restricted towards the north-west. Curiously enough, a further watch from that time until 12h. 30m. was only rewarded by the observation of one meteor, and that not a Geminid, which gave one the impression that the shower had terminated. Clouds prevented further observation. Whether the shower was more brilliant earlier in the evening cannot, so far as this place of observation is concerned, be stated. Another observer, Mr. W. E. Rolston, of the Royal College of Science, South Kensington, was also surprised at what appeared to be quite a shower of meteors on the same evening. He recorded the appearance of several meteors during the interval 11h. 15m. p.m. to 12h. 20m. a.m. G.M.T., one of which, as he describes, "an exceptionally long and bright one, leaving a long trail of reddish sparks, which lasted for about two seconds." The same observer also mapped nine true Geminids on the night of the 9th.

COMET CHASE.—Using the same elements as those we published in our last number, the following is the ephemeris for the current week.

Ephemeris for Berlin Mean Midnight.

1898.	R.A. (app.) h. m. s.	Decl (app.) ° ′	Br.
Dec. 14	10 47 51	+25 49·3	1·39
,, 16	49 51	26 6·0	
,, 18	51 44	26 23·4	
,, 20	53 31	26 41·3	
,, 22	10 55 11	+26 59·8	1·39

The comet is thus still in the constellation of Leo, and is situated approximately between 54 and 57 Leonis. It is now brighter than it was at the time of its discovery. Prof. E. Weiss thinks that it may be identical with 1867 I.

It is interesting to remark that the comet was discovered photographically near the radiant point of the Leonid meteor swarm. Four other photographs taken—two at the Yale, and two at the Harvard observatories—have corroborated its presence.

THE TOTAL SOLAR ECLIPSE OF JANUARY 22, 1898.—We have received from the Survey of India Department the report on the observations made at Dumraon, Pulgaon, and Sahdol during the recent solar eclipse. The report is divided into three sections, each section giving an account of the arrangements and observations made at the three different stations. The first, somewhat necessarily brief, is written by Mr. T. A. Pope, Assistant Surveyor-General, who had charge of a three-inch photographic doublet. With this instrument an excellent series of plates of the corona was obtained, one of which is reproduced as frontispiece to the present volume. The Pulgaon report, by Captain G. P. Lenox Conyngham, R.E., contains an interesting and well illustrated description of the camp, and the programme which the party had before them. Mr. Newall and Captain Hills, it will be remembered, occupied this station, and received valuable assistance from the officers and others present. The report on the observations at Sahdol, by Major S. G. Burrard, R.E., is somewhat more voluminous than the two preceding. In addition to a general account of the arrangements as regards the camp distribution and the preparatory work of the observers, such results as could be immediately deduced are given. Thus, for instance, we have a comparison between the temperature curves obtained on the actual and following day of the eclipse, showing clearly the drop from the time of first contact to about half an hour after totality, and the subsequent rapid rise. The large assembly at Sahdol made it possible to organise a party to make sketches of the corona. This was done, with the result that we have here thirty-one facsimiles of the hand-drawings made. After an examination of these sketches, we can truthfully remark, with Major Burrard, that "the accordance between these drawings is more remarkable than their discrepancies." The remaining portion of the report is devoted to a brief summary of the Hindu method of eclipse prediction, a chapter on future total solar eclipses in India, with twelve charts of tracts of past and future solar eclipses, and lastly to the answers to a series of questions concerning the corona and the attendant phenomena.

The volume, which is published under the direction of Major-General C. Strahan, R.E., the Surveyor-General of India, is very well illustrated, and should serve as a useful guide and source of valuable information for future eclipse expeditions.

NOVEMBER METEORS. — The *Harvard College Circular* (No. 35), which has just come to hand, describes in a brief manner an account of the preparations for observing the Leonid shower in America, and the preliminary results obtained. It will be remembered that last year Prof. E. C. Pickering organised a large staff of observers not only to make visual observations, but to record, if possible, their trails and spectra photographically. This year the organisation was even more complete, and stations were selected all round the earth in order that the number of visible meteors might be counted during the entire period that the earth passed through the swarm. The present *Circular* deals with the observations made at Cambridge (U.S.A.) and Providence, the reports from other stations not having yet arrived.

At the former town the night of the 13th was cloudy, but the 14th was clear. Thirty persons at the observatory recorded 800 meteors, not including duplicates, the maximum number having occurred at 3 o'clock in the morning, when 61 meteors east of the meridian were counted in thirty minutes. No less than 227 trails of eighty different meteors within 30° of the radiant were charted. At Providence the vicinity of the radiant point was continuously watched by at least ten observers, and 400 meteors were seen. Prof. Pickering chose this station (which is forty miles south of Cambridge) for visual determinations of parallax.

As regards the success of photography for this work, the results obtained seem very promising. Ninety-six photographs were taken at Cambridge with the Draper telescopes, and eleven with smaller instruments. Not only were photographic doublets employed, but prisms were utilised; but these, unfortunately, failed to give any record. By means of the doublets thirty-one trails of eight different meteors were photographed, three of which appeared on one plate. Four meteors were photographed at both stations, so that the parallax can be obtained photographically. A preliminary determination of the radiant point

gives the position for 1900 as R.A. 10h. 6·8m., Dec. + 20° 16m., which is 9m. following, and 38′ south of that given by Denning. Some peculiarities of the photographed trails were that they attained a maximum and then diminished as rapidly as they increased, sudden changes due to explosion were well shown, the trail was sometimes surrounded by a sheath of light, and lastly, in one case the trail remaining after the meteor had passed was recorded.

ASTRONOMICAL CONGRESS AT BUDAPEST

As was announced in NATURE of August 25, the International Astronomical Association (*Astronomische Gesellschaft*) held its seventeenth Congress at Budapest at the end of September.

The meeting was an unusually large one, and the reception by the Hungarian colleagues and the scientific and political authorities was exceedingly cordial. There were present, amongst others, the directors of the Observatories of O'Gyalla (von Konkoly), Hérény (von Gothard), Kalocsa (Father Fenyi, S.J.), Vienna (Weiss), Munich (Seeliger), Karlsruhe (Valentiner), Heidelberg (Wolf), Göttingen (Schur), Jena (Knopf), Berlin (Foerster), Breslau (Franz), Bamberg (Hartwig), Turin (Porro), Upsala (Dunér). Besides these, many well-known astronomers attended, such as Müller, of Potsdam; Nyren, of Pulkova; Pechüle, of Copenhagen; Schröther, of Christiania; Kreutz, director of the International Bureau at Kiel, and of the *Astronomische Nachrichten*; Bauschinger, director of the Institute of astronomical calculations of Berlin, and many others. The absence of English and French astronomers, many of whom form part of the Society, was much regretted, and perhaps it is due to this fact that the Congress, out of natural reserve, abstained from raising the question of the fundamental stars and constants, resolved, perhaps too hastily, by the Conference at Paris in 1896.

The first meeting was opened by President Seeliger on September 23, in the large hall of the Academy of Science, where all the subsequent meetings were also held. Von Wlassics, the Minister of Education, who afterwards offered lunch to the members of the Congress, the burgomasters of Budapest, and Baron Eötvös, President of the Academy, well known for his experiments on gravitation, attended.

In the meetings of September 25, 26 and 27, besides other affairs of the ordinary business of the Society and the confirmation of the members of the Presidency, retiring by seniority, many scientific subjects, briefly referred to here, were discussed. Prof. Schür described the new reductions of the observations of planets and comets, made at Bremen by Olbers. Such reductions are made after the original notes of Olbers, placed at the disposal of the Gottingen Observatory. Dr. A. Stichtenoth, together with Prof. Schur, takes part therein. In the first place are discussed the determinations of time made by Olbers through observations of the setting of the principal stars behind the vertical side of the tower of the observatory, then the measures of the radius of the circular micrometer adopted, by the medium of the observations of couples of stars applied to the comparison with one particular comet; and lastly, these same planetary and cometary observations. In the published papers the times of the observations and the distances along the circle of declination of the comet and the comparison stars from the centre of the ring will be given. It is hoped that it will be possible to place these important materials at the disposal of astronomers during next year.

Dr. Bidschof, of the Imperial Observatory of Vienna, gave an account of some catalogues completed by him. These contain a list of the nebulae that were determined micrometrically at the observatory of Vienna up to the end of 1897, besides a stellar catalogue, containing the results of the new observations of the southern stars of Santini, executed at the Viennese observatory.

Dr. Brendel, of Gottingen Observatory, referred to the publication of Gauss's works. Soon after the death of Gauss the editing of his works was confided to Prof. Schering, of the Royal Academy of Göttingen. Schering published six large volumes, but did not succeed in completing the publication, so that, besides the great part of astronomical subjects published in the sixth volume, and the "Theoria Motus," printed in the seventh, the numerical discussion of the perturbations of the motion of Pallas, which will occupy the remainder of the seventh volume, remained unedited. Concerning this, it is necessary to note that, Gauss having left an enormous quantity of material (above half a million of figures) on this subject, without sufficient explanation, the reconstruction of the mode of these calculations becomes very difficult, though not impossible. The so-called libration, connected with the curious phenomenon, by which seven evolutions of Jupiter correspond exactly to eighteen of Pallas, presents special interest. The eighth volume will contain additions to all the materials of mathematics and physics dealt with in the fifth. Finally, the ninth volume will be concerned with biographical matters.

Prof. Franz demonstrated that the lunar globe previous to its solidification must have been elongated in the direction of the earth by the tides produced by our planet. Whilst the theory of tides and the physical libration assigns to such elongation the small amount of 0·0001 of the radius, Gussen, from the measure of two lunar photographs in different librations, obtained the considerable elongation of 0·0500. To eliminate such contradictions between the theory and the observation, Prof. Franz has measured five lunar photographs from the Lick Observatory in various combinations, and found an elongation of the lunar globe of 0·0027. Thus a nearer approach to the theory is reached, which, however, cannot result in complete accord, through the want of homogeneity in the lunar mass. Hansen put forward the hypothesis that the opposite part of the moon was deeper, so that it had gathered on itself water and air, thus rendering animal and vegetable life possible. On this hypothesis a lively and interesting discussion ensued between Profs. Foerster and Franz.

Dr. Witt, of the Urania Observatory of Berlin, observed that a simple glance at the stereoscopic views of the moon shows a considerable elongation.

Dr. Marcuse, formerly delegate of the Geodetic Office of Potsdam, in the Sandwich Islands, for the study of the variation of latitudes, called attention to the necessity of generally extending the methods of photographic registration of the observations of latitudes, applying them in quite a general manner to the geographical determinations obtained in travelling. He considers, having had occasion from 1893 to superintend the construction of a photographic zenithal telescope, and afterwards to use it, that the photographic registration of the measures of altitudes and transits can be easily obtained by means of a convenient universal instrument, adapted to visual as well as photographic measuring; and that with it, surety and precision are gained. An instrument for that purpose is being constructed.

Dr. Max Wolf, of Heidelberg, so well known for his photographic discoveries of small planets, spoke on the researches made by him on an objective worked by Dr. Pauly in Jena, with the aperture of 21·2 cm., and the focal distance of 445 cm. It is formed of the new glass of Jena, and must possess better chromatic corrections than the old systems. In fact, the investigation with the spectroscope has shown that the colours are exactly comprised from the extreme red to the blue; only towards the G line the colours begin to deviate. A comparison of the curve that represents the position of the focal points corresponding to the various colours, with analogous curves given by objectives of Fraunhofer, Grubb and Clark, shows the superiority of the objective of Pauly to the best anterior ones. While the deviation of the focus in the middle of the blue scarcely reaches to 0·00003 of the focal distance, that of 0·00065, determined by Clark, is far the least considerable of those remaining. The correction of sphericity is also small. Many delicate couples of stars are separated; *e.g.* η Coronae (distance 0·″4), μ_2 Bootis (0·″9), ι Coronae (0.″4), λ Cassiopeiae (0·″6), μ Cygni (2·″9), ξ Hercules (0·″5), $o\Sigma$ 338 (0·″7), Σ 2695 (0·″9), Arcturus in the angle of position 120° appears lengthened; ζ Bootis and 52 Arietis could not be resolved. The size of the stellar discs amounts to 0·″24 for the sixth magnitude, to 0·″15 for the eighth. Dr. Pauly added some explanations on the manufacture of the new objective. The first attempts to eliminate the secondary spectrum go back to the year 1886; but then the glass used was not suitable. Only for two years has it become possible to obtain a new glass perfectly well adapted, the dispersive properties of which insure absolute elimination of the secondary spectrum. The pictures of the sun and moon are surprising, especially of the moon.

Prof. Porro presented a paper by the new member of the Association, Prof. Vito Volterra, of the Turin University, on the mechanical theory of the motions of the terrestrial pole. In this paper are recapitulated the results of a more extended work, which will be published in *Acta Mathematica*.

Following upon this communication, Prof. Porro gave an account of the present state of the calculations being made at New York and Turin for a new reduction of the observations of Piazzi, and for the compilation of a stellar catalogue founded on the same. According to arrangements made between Dr. Auwers and Prof. Schiaparelli, the work is divided between Dr. Herman S. Davis, of the Columbia University Observatory, and Prof. Porro. Mrs. Coreita R. Davis shares in it at New York, Dr. Vittorio Balbi at Turin.

A third notice given by Prof. Porro concerns the eighteen tables, in which he has had reproduced in facsimile the original sketches of the constellations, drawn by Francesco Bianchini in the seventeenth century.

The sketches contain the first essays on exact relative ocular determinations of the stellar magnitudes, executed by a method not differing essentially from that suggested and applied a century and a half later by Herschel. Argelander and Schiaparelli had deplored the loss of these papers, which ought to be of service for the historical study of the variable stars. The speaker had been able to find the manuscripts in a code of the Capitular Library of Verona, to which Bianchini, when dying, had bequeathed all his books; and had found that, without giving to the afore-named study the contribution expected by Bianchini and Montanari (of which also observations are reported), the papers themselves furnish the first document of exact determination of the relative magnitudes of the stars, which is recorded in the history of astronomy, resolving the query propounded by Argelander in his paper, "De Fide Uranometriae Bayeri."

Dr. Fritz Cohn, of Königsberg, described some general results of a new reduction of the most ancient meridian observations of Bessel. Of the observations made by Bessel in the years 1814–19, none had been published till now, save the known Fundamental Regiomontan Catalogue of Maskelyne's thirty-six stars for the epoch 1815. Bearing in mind the date of the observations and the name of the observer, it had been thought desirable to undertake a reduction of the materials gathered together. As the fundamental problem it seemed necessary to show the systematic errors of the Besselian method, and eliminate the damaging effect. Inasmuch as the presentation of the systematic errors in Bessel's catalogue depends considerably on the method of reduction adopted, it was needful to seek for a method that should limit as much as possible the influence of the systematic errors on the results. Applying a method studied purposely to such an end, a considerable improvement of Bessel's catalogue was obtained. But a perfectly satisfactory result could not be obtained till the cause of the error was discovered in a different distribution of the passages of the stars between day and night, and until such cause could be exactly calculated. After such a result it would be desirable that also in other series of observations of fundamental stars, especially ancient ones, search should be made of eventual systematic errors, because it is to be expected that from the consideration of these the accuracy of the results would gain considerably.

Prof. Foerster read a brief notice on some questions connected with the length of the year and the calendar. The numerous numerical data on which his discourse was founded do not lend themselves to a recapitulation of the interesting matter treated with the usual ability by the illustrious director of the Berlin Observatory.

On the measurement of the brightness of the nebulae and the clusters of stars, spoke Dr. Holetschek, of Vienna. He has been occupied for several years in determining the luminous impression made by the light of a comet through the weakest telescope in which the comet itself is visible, and eventually by the naked eye, noting the stars that are visible with equal facility or with equal difficulty in the same conditions. In this manner it has been possible for him to represent such luminosity with numbers, and now he has begun the application of the same system to nebulae and clusters of stars also. Manifestly, the method does not lend itself equally well to all classes of similar celestial objects: in particular it is not adapted for nebulae illuminated diffusely and uniformly, and for clusters of stars spreading over a wide space, as those in the Classes VII. and VIII. of Herschel.

Applying his method to objects of the first two classes of Herschel, Holetschek has found, for instance, that the brightness of the Pleiades corresponds to magnitude 1·5, that of the Presepe of Cancer to 4, of the nebulae of Andromeda to 5·3. Messier having compared the brightness of the comet 1779 to that of four different nebulae, of brightness 6·5; 7; 8·7; and 9·6, the author has been able to extract good values for the brightness of the comet. In the determinations executed between 1886 and now, he did not succeed in recognising any variations in the brightness of the nebulae under observation.

Prof. R. von Kövesligethy, of Budapest University, referred under the title "Ueber die Beiden Parametergleichungen der Spectral Analyse," on the studies just finished by him in the field of spectral analysis, the scope of which is to found astrophysics on mathematical bases. He shows how the two fundamental equations of the theory of heat are destined to have the same importance in astrophysics as the principles of mechanics have in astronomy, and that it is only now necessary to determine by observation the quantities that figure in such equations. To such an end the equation of emission is formed very simply in function of the length of the wave, and of two parameters that depend on the nature of the bodies; and it is not difficult to prove that the proceeding is severe, recurring to the proposition of Clausius on the radiation and to the equations of dispersion. Besides, it represents perfectly a series of bolometrical measures of the spectrum. The author insisted on the application of his theory to very important questions, also of mathematical astronomy, as the determinations of the parallaxes, the volume and densities of the heavenly bodies.

Father Fenyi, S.J., spoke on the observations of solar protuberances at the Kalocsa Observatory from 1884. He noted, first of all, that the greatest heights of the protuberances observed evidently depended upon the greatest amount of solar activity. With regard to the nature of the protuberances, he observed that they appear in the absolute vacuum, according to the theory of Schmidt, by which the density of the critical stratum around the sun could be determined with accuracy; but hydrogen cannot have a greater density than that of the critical stratum, and hence the maximum of density possible to hydrogen at every height can be determined. If this density be determined only for a height of 25″, it is seen directly that no trace of hydrogen can exist there; because on a volume equal to that of the sun a single molecule alone would fly from it. The theories that contradict this result are, therefore, to be rejected.

Prof. Hartwig, of Bamberg, called attention to the star SS Cygni, which, together with U Geminorum alone, forms a special class of variables, that offers special occasions, by its connection with new or temporary stars, to the study of these mysterious stellar bodies. The character of this class consists of an unexpected lighting up, followed by a rapid increase of magnitude, after which comes a slow return to the usual brightness. The spectographic study of SS Cygni seems possible for the large instruments now in activity, and would certainly furnish useful information on the causes of similar mysterious phenomena.

Another communication was made to the Congress by Prof. Kreutz, who referred to the actual state of the calculations of cometary orbits.

Among the numerous visits made by the members of the Congress to noteworthy places in the city and in the kingdom of Hungary, special mention should be made of the O'Gyalla Observatory, where the splendid hospitality of Dr. von Konkoly was not less admired than his munificence in preparing and presenting to the State a magnificent collection of instruments, designed by him and constructed under his direction, and of the Institute of Physics of the Budapest University, where they attended the experiments on gravitation of Baron Eötvös. The general impression that remained was of sincere admiration for the very notable progress made in the field of science by the country of Hungary, whose name was given to a new planet discovered by Wolf.

FRANCESCO PORRO.

RECENT PROGRESS IN ORNITHOLOGY.[1]

As the editors of *The Ibis* have already remarked in their preface to the volume for the present year, one of the leading ornithological events of 1898 is the completion of the "Catalogue of Birds." The twenty-sixth volume of this work, prepared by Dr. Bowdler Sharpe and Mr. Ogilvie Grant, the only one required to finish the series, will, I am assured, be

[1] Address given by Mr. Sclater at the opening meeting of the British Ornithologists Club, on October 19.

laid before the Trustees at their next meeting, and be ready for issue very shortly afterwards. Thus, after a period of twenty-five years, this most important piece of ornithological work has been brought to a conclusion. No human product is perfect, and the Catalogue has been, and will be, the subject of many criticisms. One obvious defect in it is its want of uniformity, the various authors having been permitted, owing to the wise discretion of the authorities, very liberal opportunities for the expression of their own views in their respective portions, although a general adherence to one plan has been rightly insisted upon. But when the enormous amount of labour required for this work, and the absolute necessity of employing more than one author upon such a huge task are considered, it will be obvious that greater uniformity was practically unattainable. In the case of the "Catalogue of Reptiles and Batrachians," where the series of specimens and species was not so large, the herpetologists are fortunate in having had the whole of the work performed upon a uniform system by the indefatigable energy of a single naturalist.

The "Catalogue of Birds," as complete in twenty-seven volumes, gives us an account of 11,614 species of this class of Vertebrates, divided into 2255 genera and 124 families. It has been prepared by eleven authors, all members of the British Ornithologists' Union, and with one exception, I believe (who is not a resident in England), now or formerly members of this Club. I think it will be universally allowed that we have, in this case, a great and most useful undertaking brought to a successful conclusion.

Another good piece of ornithological work, likewise the product of a member of this Club, which has just made its appearance, is Mr. Beddard's volume on the "Structure and Classification of Birds." It seems to me to be a most useful manual on this subject, profusely illustrated, and full of convenient references to further information on various points which it would have been impossible to compress into a single volume. It will be found to be a mine of wealth to those who choose to dig in it, and contains a good summary, not only of the results arrived at by Mr. Beddard himself, but also by Garrod and Forbes, his illustrious predecessors in the office which he holds.

Mr. A. H. Evans, whose volume upon Birds for the "Cambridge Natural History" we have been long expecting, informs me that this work is finished, except the index, and will be shortly published. We shall all welcome its appearance with the greatest pleasure. A second work that Mr. Evans, together with Mr. Scott Wilson, is engaged upon is the "Aves Hawaiienses," of which we have long been waiting for the final part. This, I am assured, is now in a forward state, and is likely to be issued without further delay.

From information received from Mr. Rothschild, I am pleased to be able to say that his somewhat parallel illustrated work on the "Avifauna of Laysan," of which the last part was issued in 1893, will also be shortly brought to a conclusion, and that the third and final part will be issued in the course of next year. Taken together, these two works will form a most valuable contribution to our knowledge of the Avifauna of the Northern Pacific. I must also not forget to mention, amongst recent contributions to our science, the excellent work of Dr. Meyer and Mr. Wiglesworth on the birds of Celebes—one of the most elaborate and complete ornithological monographs on the birds of a special district ever prepared. Celebes, I may remark, as a debatable land between the Australian and Oriental regions, was in special need of the full treatment and discussion which it has here received from the authors of this work.

But the brethren of the B. O. C. and their friends, I think I may say, are at present not less active in the field than in the cabinet. We are fortunate in having with us to-night the two principal members of the new expedition to Socotra and Southern Arabia, which will leave England on the 28th inst. It will, of course, take up natural history in every branch, but with Dr. Forbes and Mr. Ogilvie Grant as its leaders, and a trained taxidermist in attendance, we need not fear that the interests of Ornithology will in any way be overlooked. In Socotra itself much has been already done, but little or nothing has been ascertained ornithologically of the southern coast of Arabia, and we know, from Bent's writings, that even in this commonly supposed barren district, bird-life is abundant in certain spots, which we trust may be within reach of the Expedition.

Besides the Socotran Expedition many other explorations by various members of the B. O. U. are in progress or in contemplation. Captain Boyd Alexander, who has worked so well in the Cape Verde Islands, is struggling through the middle of Africa from the Cape to Cairo. Under present circumstances he seems likely to come out successfully, and will, no doubt, bring information on birds, if not specimens, with him. Mr. Lort Phillips hopes to return to his favourite quarters in Somaliland during the course of the present winter, and expects to get together the supplementary materials still required for the preparation of his proposed work on the birds of that most interesting country. Mr. John Whitehead, who has added so much to our knowledge of the zoology of the Philippines, proposes to return to the same country very shortly, in order to continue his researches in a field which he knows so well and in which he takes such great interest. Before leaving, he has placed in the hands of the editors of *The Ibis* a series of valuable field-notes on the birds collected during his last journey. These will appear in the forthcoming volume of our journal. Mr. Alfred Sharpe, C.B., who is shortly returning to his post in Nyasaland, promises to continue the employment of collectors in different parts of that Protectorate, the zoology of which he, following in the footsteps of Sir Harry Johnston, has already done so much to investigate.

Finally, I may remark that, as will be seen on turning over the pages of contents in the last volume of *The Ibis*, we have correspondents interested in our favourite subject in nearly every part of the world, and that the great difficulty of the editors is to compress so many valuable contributions within the compass of an annual volume.

Before resuming my seat, I wish to say one more word. Our Government, in connection with that of Egypt, has just taken possession of an enormous district in Africa, probably nearly equal to half Europe in extent. It sternly warns all intruders off, even when they are alleged to be of "no political influence." When it comes to regulate the administration of these new territories, it is to be hoped that the interests of natural history will not be entirely overlooked. Although the Upper Nile districts have been traversed and investigated by many well-known naturalists, there is still very much to be done in these teeming regions of animal-life. We Englishmen are ready and willing to undertake, by individual efforts, much work that in other countries is provided for by State explorers; but it is not too much to expect that our Government should at least help us by providing adequate facilities and occasional assistance, and even, perhaps, by contributions to the expensive process of bringing the results thus acquired completely before the world.

THE ECONOMIC EFFECTS OF SHIP CANALS.

In a paper submitted to the American Academy of Political and Social Science by Mr. J. A. Fairlie, on "The Economic Effects of Ship Canals," it is pointed out that while the construction of the North Sea Canal doubled the tonnage of the shipping of Amsterdam in the first six years after it was opened, the effect was purely local, as will be that also of the Manchester Ship Canal; and that although the Welland, Corinth and Kiel Canals have larger possibilities, their actual consequences have as yet been small. With the Suez and Sault Saint Marie Canals the results have been both important and far-reaching, and have affected the trade of the world. Both these canals have led to a rapid change in the material and character of the vessels used; to important changes in the sources of production; to the development of the growth of wheat in the countries which they serve; and to a large reduction in the cost of bread and other food in this country.

The Suez Canal opened in 1870 with a traffic of 486 vessels having a tonnage of 436,000 tons; in 1891, the record year, the traffic had increased to 8,700,000 tons. The new route by effecting a saving of 3000 miles on the voyage from the ports of Western Europe to the East, or almost half the distance to Bombay, brought about a complete revolution in the character of the shipping business to the East. By the Cape route coaling places were few, and the facilities for coaling expensive; the consequence was that owing to this, and the large space occupied by coal, to the exclusion of paying cargo, sailing vessels were more profitable than steamers. By the canal, steamers can coal at Gibraltar, Malta, Port Said and Aden; consequently,

owing to these facilities and the shorter distance, sailing vessels soon became superseded by steamers, and it was estimated that 2,000,000 tons of vessels were thus thrown out of employment. Under the old system, when voyages from India took the greater part of a year, and the time of arrival could not be calculated within a month or two, it was necessary to keep large stocks to meet the varying demand for goods, and hence the erection of the enormous range of warehouses at the India Docks. Steamers by way of the canal make the voyage in thirty days, and the time of their arrival can be regulated within a day or two; shorter voyages and punctuality of arrival make it possible for merchants to order direct from the East, and hence less capital is required and the cost of warehousing saved. The Suez Canal has had a material effect in fostering the growth and export to this country of Indian tea, which has increased from 11 to 120 million pounds. The export of rice from India has also enormously increased since the opening of the canal, and now constitutes the largest single item in the export trade of India. When the only route was round by the Cape the difficulty in transporting wheat, owing to its liability to heat during the voyage, and the loss from weevils, made the export of grain unprofitable. Since the opening of the canal India has become the second exporting country of the world, the exports of grain amounting now to over 50,000,000 bushels.

Other merchandise, both of import and export, has been affected to a less degree; the shorter route has also rendered possible the export from Australia and New Zealand of very large quantities of meat, fruit and other food products.

The Saint Mary Falls Canal, commonly called "The Soo," has now a traffic even larger than that of the Suez Canal, and exceeds the total foreign trade of the port of New York. The development of the trade now carried on over the Great Lakes is almost entirely due to this "Soo" canal. The size of vessels engaged in the navigation in 1870 averaged 175 tons; now there are five lines, owning sixty steamships of from 1750 to 3000 tons. The increase in trade is due in a great measure to the opening out of the iron mines of northern Michigan and Wisconsin, which have been made available by the canal route from the mines to the ports in the southern lakes. But the most important factor in the increase of the navigation is the transport of wheat and flour, the low rates at which these can be carried by water encouraging the growth over a very widely extended area of country. The other resources which have been developed by the construction of this canal are timber, coal and copper. One conspicuous feature due to this canal is the immense increase in population in the Lake Superior region and the development of towns.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE Anthropological Section met in the Park Place Schoolroom, under the presidency of Mr. E. W. Brabrook, C.B., ex-President of the Anthropological Institute.

On Thursday, September 8, the morning's programme consisted mainly of papers on physical anthropology.

The sixth annual Report of the Committee on the mental and physical deviations from the normal among children in public elementary and other schools was read by Mr. White Wallis, and gave a further account of those children whose mental and physical condition renders them unfitted for the public education provided in ordinary elementary day schools. The new information has been mostly obtained by studying the correlations of the cases, and the facts tabulated show that great difficulties must arise in making any provision for the proper care of these children, who show a much greater tendency than average children to become delicate under an adverse environment. The large proportion of both boys and girls who present "abnormal nerve-signs" shows the importance of trying to remove each such sign by carefully adapted physical training, and that the improvement of the brain condition of such children below the average in mental and physical development requires skilled teachers and good hygienic surroundings.

Mr. O. H. Howarth read a paper on human life at high altitudes, with the object of determining whether the adaptability of man to extreme conditions is of comparatively recent development, or of gradual growth. He exhibited an object which he regarded as a stone celt, found at an elevation of 7700 feet in the Rocky Mountains in Colorado. As causes of human inhabitation of extreme altitudes, he named the pursuit of industries impracticable elsewhere, and seclusion for religious purposes, and enumerated the conditions favourable and unfavourable to the persistence of human life under these conditions. He described numerous specialised superstitions; especially the impulse to establish cults on high peaks, and the belief in disembodied spirits, leading to a variety of precautions to prevent their interference. In the discussion which followed, Dr. Beddoe pointed out that Tibet, which was the highest average altitude in the world, was the only place in which real theocracy existed, and that the shepherds in remote parts of Australia often became demented because they were so much alone. Dr. Francis Galton thought it would be worth while to observe the behaviour of animals in high altitudes. Prof. Tylor suggested that some attention might also be directed to the collection of literature dealing with this subject. Mr. C. H. Read regarded the object exhibited by Mr. Howarth as a purely natural production, not a manufactured implement. Dr. G. A. Dorsey and Dr. J. G. Garson continued the discussion. Mr. Howarth briefly replied.

Miss M. A. Ellis presented a note on the human ear as a means of identification, stating that ears do not change shape after childhood, and classifying the great varieties of shape by marking off the *helix* into five divisions. Various types of ears were exhibited, and a brief discussion followed.

Mr. K. Minakata's paper on *Tabu* in Japan was read in abstract.

Mr. G. Leith read an important paper on a large and varied collection of stone implements from South Africa, describing the situation and characteristics of the bushmen's haunts, in some of which were found implements and other signs of occupation, just as they had been left years ago; and remarking upon the various types of stone implements which are found both in the cave deposit, and in the talus in front of the cave. With these poisoned arrows the bushmen were a dangerous enemy to the Boers, even when the latter were equipped with firearms. The investigation of Lighthouse Cave, at Cape St. Blaize, led to the discovery of many fine specimens of skinning knives, scrapers, and flaked implements, indicating that it had been a place for the manufacture of these implements for many ages. Alluding to his researches in various beds of gravel at various altitudes in which he discovered large numbers of palæolithic stone implements of very remarkable size and shape, he classified the latter, according to their position, into neolithic or modern, palæolithic or ancient, and eolithic. The evidence of these gravels proved without doubt, in his opinion, that South Africa was the home of man at a very remote period of history. The eoliths found there corresponded exactly with the plateau implements found on the Kentish Weald by Mr. Harrison. Prof. Dawkins did not think that the evidence was clear as to their belonging to the Gravel ages, and had no doubt that he could find a parallel from North America for the specimens produced.

Mr. F. T. Elworthy described a number of Roman symbolic hands from Pompeii and elsewhere, of the kind known as *Mano Pantea*; contending that these hands are not votive offerings, but in fact the Roman Penates. Mr. A. J. Evans and Mr. E. S. Hartland pointed out that these hands all belong to the late heterogeneous cults of the early empire, and have no connection with the indigenous family cults of Italy. Mr. J. L. Myres described other examples exhibited in the British Museum, one of which bears a definitely votive inscription. Bishop Brownlow commented on the Christian benedictory use of the gesture represented in these pre-Christian hands.

Mr. H. Warington Smyth described the river craft in use among the Siamese, explaining the construction of the "dug-out" Me Kawng boats, and discussing the various native types. To this was appended a brief description of the simple fourteen-reed instrument in use among the Lao of the Me Kawng Valley, illustrated by an example of this characteristic and monotonous music.

On Friday, September 9, after the President's address, Dr. Beddoe gave a summary account of the mediæval population of Bristol, based on two series of skulls, the one mediæval, the other probably of the eighteenth century, disinterred on the occasion of the removal of St. Werburgh's church, and on certain lists of surnames of various dates. He found the mediæval skulls very generally small, short and broad (cephalic index 80·0), while the later ones exhibited the same long types that characterise the present population of

Bristol and the surrounding districts (index 76·6). He ascribed the mediæval bráchycephalism to the large proportion of people of French descent, which was indicated by that of French surnames, these latter having gradually declined in number ever since the fourteenth century.

Prof. H. A. Miers, F.R.S., read a note on the origin of stone-worship, in which he pointed out that when meteorites fell in early times, they must have provoked religious awe; quoting instances among recorded falls in which this was certainly the case, and some in which the meteorite became an object of worship. Mr. Arthur Evans pointed out in reply that the meteoric theory of stone-worship had in fact been formerly dominant, but could not be held to account satisfactorily, in a large number of cases, for the observances associated with the worship of stones.

Prof. C. Lloyd Morgan gave a short account, with lantern illustrations, of the camps and megalithic remains to be visited during the meeting in connection with the excursions.

Mr. A. L. Lewis sent a note on the circles of Stanton Drew.

A description of the megalithic monuments of Dartmoor, by Mr. P. G. S. Amery, was postponed to Wednesday's session.

The afternoon session was held in the Princess Theatre, Park Row, and attracted an audience of nearly a thousand persons. Prof. E. B. Tylor, F.R.S., discussed the survival of palæolithic conditions in Tasmania and Australia, with especial reference to the modern use of unground stone implements in West Australia; pointing out that the stone implements from Tasmania, the making and use of which by the natives came under the observation of the colonists during the first half of this century, have a character which may be called quasi-palæolithic. They were fragments or flakes of stone, in no case ground, but edged by chipping on one face only, and trimmed so as to afford a grasp to the hand, no haft of any kind being used. These instruments correspond to some extent with scrapers, &c., belonging to the Drift and Cave periods in Europe; but their general rudeness, and the absence among them of symmetrical double-edged and pointed implements like the flint picks of Old World palæolithic times, place the modern Tasmanians at a distinctly lower stage than the Europeans of the mammoth period. The stone implements found in Tasmania, of which some good collections have now been made, indicate a state of the Stone Age in past times not essentially different from that found in actual existence before the disappearance of the native population. These quasi-palæolithic implements, old or new, have to be considered apart from the few cases of ground stone hatchet blades fixed in handles, which are now admitted to have been introduced in modern times by Australian natives.

The purpose of the paper was to offer evidence making it likely that the early Stone Age condition characterising Tasmania extended within no distant period over the whole Australian continent. A native Australian hatchet hafted with gum on a stick-handle was exhibited, lent by Mr. W. Ayshford Sanford, of Nynehead Court, Somerset, who brought it half a century ago from the Perth district of West Australia. The blade of this instrument, with its unsymmetrical edge formed by chipping along one side of the original flake, is simply indistinguishable from the ordinary Tasmanian form placed beside it. Prof. Tylor stated that, unwilling to judge hastily from a single specimen, he had for years been in correspondence with anthropologists in Australia as to the presence there of such implements, and had lately, through communications from the Bishop of Tasmania and Mr. Alexander Morton, of the Hobart Museum, received intelligence that the latter, than whom no one better understands the Tasmanian implement question, has on a late journey to the little-known Murchison district in West Australia, while not meeting with ground stone axes, found the natives using chipped stones quite similar to those used by the Tasmanian aborigines, as shown by photographs sent for comparison. These quasi-palæolithic implements not having yet been dispossessed in this district by the ground stone hatchets, which apparently were introduced from the Torres Straits region, it would seem that this neolithic invasion was of no remote date, and that the vast area including Australia as well as Tasmania may have been till then peopled by tribes surviving at a level of the Stone Age which had not yet risen to that of the remotely ancient European tribes of the Drift gravels and limestone caves. While disclaiming any hasty inference, Prof. Tylor called attention, from this point of view, to the importance of, and the similarities between, the modern Australioid skulls and the prehistoric skulls of Neanderthal, Spy, Padbaba, &c.

On Saturday, September 10, Prof. Tylor opened the morning session by introducing the final report on the north-western tribes of Canada. He pointed out that, while the work of the committee has materially advanced our knowledge of the tribes of British Columbia, the field of investigation is by no means exhausted. The languages are still only known in outline. More detailed information on the physical types may clear up several points that have remained obscure, and a fuller knowledge of the ethnology of the northern tribes seems desirable. Ethnological evidence has been collected bearing upon the history of development of the culture area under consideration; but no archæological investigations have been carried out which would help materially in solving these problems. For this reason Prof. Tylor thought it was a matter for congratulation to know that the ethnological investigation in British Columbia will not cease with the operations inaugurated by the committee, but was now entrusted to the committee for the ethnological survey of Canada, the second report of which was to be read during the morning. He finally bore testimony to the very high value of the work done by that committee.

Mr. J. L. Myres then read a condensed abstract of the complete final report of the committee. It consists of two parts: (1) Report of the investigations into the physical characteristics of the tribes of British Columbia, by Dr. Franz Boas and Mr. Livingston Farrand; (2) a summary of the work of the committee in British Columbia, by Dr. Franz Boas.

Sir John Evans, commenting upon the report, said that one question that arose was whether the committee had been able in the course of their labours to acquire any of those old personal objects which formed such an interesting subject in the report. He knew that in the museum at Victoria there was a collection of the antiquities of the north-western tribes of Canada, but he believed that the bulk of the objects collected in Canada were still in the museum of New York. This circumstance, however, was largely due to the greater liberality of the United States Government. It would be a graceful act if the authorities of that museum were to present to the British Museum a typical collection of the objects that Dr. Boas had obtained, assisted as he had been by the British Association. When in Vancouver and Victoria he had thought it a great pity that the many objects collected from the original inhabitants of the country had not found their natural home within the British dominions. Dr. Dorsey, he was sure, would agree with him that there was an abundance of material from which a selection could be made for the mother country. In conclusion, he asked those present to express their pleasure that the labours of the committee had terminated so satisfactorily.

Dr. G. A. Dorsey, of Chicago, stated that one of the objects of his present visit to England was to arrange for the transfer of some portions of the collection under his care to museums in England. He gladly testified, from his own practical experience, to the value of the reports of the committee as a guide-book to the tribes which they described. He further pointed out that Dr. Boas was not now in the service of any association, but was employed by the New York Museum, the directors of which had placed at Dr. Boas' command something like 1200*l.* for equipment purposes.

The President endorsed the views of Sir John Evans and Dr. Dorsey as to the value and importance of the work of the committee and its embodiment in the pages of the report.

Mr. Hartland expressed the hope that the whole series of reports, some of which are out of print, might be republished in a convenient form; and a resolution to that effect was subsequently sent up by the Sectional Committee to the Committee of Recommendations.

Mr. A. Krauss read a paper, illustrated by lantern slides, on the Tarahumare people of Mexico. He showed that the Tarahumaris lie in the most inaccessible portions of the Sierra Madre of Northern Mexico. They are ignorant and primitive, and many still live in caves. What villages they have are at altitudes of some 8000 feet above the sea level. They are a small and wiry people, with great powers of endurance. Their only food is pinoli, which is maize parched and finely ground. They have a peculiar drink called teshuin, also produced from maize and manufactured with considerable ceremony. The language of these hillmen is limited to about 300 words, and their imperfect knowledge of numbers renders them unable to count beyond ten. The religion they have seems to be a distorted and imperfect conception of Christian tradition mixed with some of their own ideas and superstitions. Miss Zelia

Nuttall summarised her own observations of the same peoples.

Miss Mary A. Owen contributed a note on the myths and customs of the Musquakie Indians.

Mr. C. Hill-Tout sent photographs of newly-discovered rock drawings from British Columbia.

The second report of the Committee of the Ethnographical Survey of Canada stated that the investigation presents two main branches: (1) that dealing with the white races, and (2) that dealing with the aborigines or Indians. These, however, are not entirely distinct, for a particularly interesting line of inquiry is that relating to the Métis or "half-breeds," resulting from the intermixture of the whites and Indians.

Three sets of anthropometric instruments have been purchased, and distributed to Mr. Charles Hill-Tout, of Vancouver; to Mr. A. F. Hunter, of Barrie, Ontario, who has associated with him Dr. F. Tracey, of Toronto; and to Dr. A. C. Hebbert, of Montreal. A camera, specially adapted to its work in the field, has been placed in the hands of Mr. Hill-Tout.

Communication has been opened with the Committee appointed by the American Association for the Advancement of Science for an Ethnographic Survey of the United States.

The several provincial governments of Canada have been approached for the purpose of obtaining, if possible, grants in aid of the work of the Committee. Nothing has, however, so far resulted from the communications referred to in the way of material aid; but Mr. David Boyle has been commissioned by the Government of Ontario to obtain photographs of the Indians of the province in connection with his investigations of Iroquois religious rites. Proceeding upon the lines adopted by Mr. B. Sulte in regard to the province of Quebec (whose results form Appendix II. of the Committee's Report), a similar inquiry has been undertaken by Mr. A. F. Hunter in regard to the composition of the population of the several counties of the province of Ontario. In British Columbia Mr. C. Hill-Tout has been able to do some work among the Haida Indians, and his results are presented in Appendix I.

On Monday, September 12, Miss A. G. Weld exhibited an early Cinghalese bronze image of Buddha, found in 1886 on the estate of Baltrasna, about 15 miles from Kells, by a labourer digging deep into a bog. Mr. C. H. Read accepted the image as a genuine work of Buddhist art, but quoted the frequent discovery of Chinese porcelain seals on Irish sites, which, like the figure in question, were probably not imported before the establishment of the tea trade. Sir John Evans pointed out that a bog would offer a safe place of concealment for stolen property. Dr. Beddoe stated that there was evidence, which was at least suggestive, that Buddhist missionaries did at some remote period reach these islands.

Mr. W. Crooke, late Director of the Anthropological Survey of the North-western Provinces and Oudh, read a paper on the jungle-folk and other Dravidians of Northern and Central India, describing the character of the country occupied by these races, their environment, food-supply and industries, and considering, mainly on the evidence of anthropometry, the relations between these jungle races and the peoples inhabiting the great northern plains. The suggestion that they were Mongoloid was dismissed as contrary to evidence recently collected. There was probably an original Negrito element in the earlier Indian races, but the existing traces of it appear hardly elsewhere than in the Veddas and the Todas. The existing Dravidians possibly represent a later emigration from the African continent, possibly reaching India by a route more northerly than that taken by the Negritos. In regard to the preponderate Dravidian element in the existing races, he briefly discussed the measurements collected by Mr. Risley and himself, and while generally accepting the conclusion that the effect of the Aryan invasion was more social than racial, he emphasised the need of a more extensive collection of measurements both on Indian soil as well as in Eastern Africa. He then proceeded to note survivals of primitive custom among the Dravidians. A discussion followed in which Dr. Beddoe, in conflict with Mr. Risley, asserted the existence of a considerable Aryan element among the present races.

Mr. Sidney Hartland desired to emphasise the value of the work done by Mr. Crooke in his inquiries among the races of the North-west Province and Oudh, and referred to the fact that ethnological work was positively discouraged among its officials by the Indian Government. Any one who realised the already very complex character of the facts relating to the native races, and the still increasingly complicated differentiation of new sub-castes and sections, must come to the conclusion that the amazing indifference of the Indian Government to ethnological questions was nothing short of suicidal. He would be glad if a representation could be made to the Indian Government urging the pressing importance to the Indian Empire of an exhaustive and sympathetic study of the races under its care.

The President heartily associated himself with the suggested appeal to the Indian Government.

An *ad interim* Report of the Torres Straits Anthropological Expedition was read, to the effect that Murray Island was reached on May 6, where, in the course of a fortnight, a number of anthropological and psychological observations were made. Delena was reached on May 27, and Port Moresby on May 31. In the absence of the Governor, Sir William Macgregor, Mr. Musgrave gave every assistance. Short visits were paid to Kaile, Kappakappa, Hula, Babaka and Kerepunu. Subsequently a short excursion was made to the Astrolabe Range. Drs. Rivers, MacDougall and Myers have obtained a large number of observations in experimental psychology, and the whole of the party have enjoyed good health.

Mr. R. E. Guise, in a paper on the tribes inhabiting the vicinity of the mouth of the Wanigela (Kemp Witch) River, New Guinea, described the tribes of Buláa, Kamali, Babaka, and Kalo.

Mrs. Isabella Bishop read an instructive paper on the Mantzu of Western Sze-Chuan. She entered upon the territory of the Tssu-Su of Goms and lived for some weeks among the Mantzu, being lodged either in their houses or on their roofs. She described the aspect of their villages and their dwellings, their devotion to Lamaistic Buddhism, their system of government, and their marriage and burial customs. Their most noteworthy characteristic was the position accorded to women, who were as unfettered as in England and America, and were on an absolute equality with men, possessing legal rights to property. She minutely described the dress and ornaments of both sexes, showing their occupations and amusements, and pointed out certain resemblances to the Lolos of Yunnan. They had their own language, but it was written in Tibetan characters. Their physiognomy was European in expression as well as feature, and recalled that of the Latin races. Mr. Archibald Little described some of his own experiences in the region, and characterised the inhabitants as being polite and hospitable. They seemed to be wedged in between China and Tibet; and how they came there appeared to be an ethnological puzzle, as their appearance was similar to the high-class Italian. Mr. Warington Smyth commented upon the characteristics of the country.

Sir T. Hungerford Holdich's paper on the Afridis and Swatis was postponed, owing to the serious illness of the author.

On Tuesday, September 13, Miss Mary H. Kingsley read a paper on West African conceptions of property, the object of which was to give some idea of the law and nature of property among the peoples of true Negro stock. The geographical distribution of the true Negro stock is a subject worthy of attention for several reasons. One is that among these peoples were found the most highly developed form of native African culture; another, that in the matters of physical and mental characteristics the true Negro differs greatly from the better-known Bantu stock. A high percentage of error had at present been attained by the failure to recognise these differences, and thereby the work of Sir A. B. Ellis on the true Negro, and that of Bastian on the true Bantu, had not yet been given its full scientific value. The three kinds of property existing in West African culture are (1) an ancestral property of the tribe ("stool" or "cap" property); (2) family property in which every member of the family had a certain share, to which every member had to contribute, and on which every member had a claim; (3) private property, acquired by personal exertion (over and above that made in co-operation with other members of their family) gained by gifts, or made in trade by the exertion of superior trading ability. Each of these kinds of property was equally sacred in the eye of native law. The only kind that could become another kind of property was the private. Stool property and family property remained of their kind for ever, and could not be alienated, though liable, with all the other kinds, to meet debt. Wealth was divisible into (*a*) the means by which property could be acquired and developed, to which division belonged wives and slaves; (*b*) property in power over market rights, utensils, canoes, arms, furniture, and trade goods. Property was guarded by and existed under the law represented by the cult of the law

god, and by the influence of religion. The President said that so elaborate a legal system, with such sound equitable principles, had seldom been brought before the Association. Sir William Crookes expressed his great admiration of the paper, and hoped that Miss Kingsley would read similar papers at future meetings.

Mr. H. P. FitzGerald Marriott then read a paper on the native secret societies of the West Coast of Africa. These societies maintained the religious and social principles of the people, and administered justice according to native law and custom. Some of them were merely temporary, such as the lesser Purroh of certain parts of Sierra Leone, of which white men spoke; others, again, were ancient tribal institutions, such as the secret religious or State Purroh, with its grand council, of which most people were unaware. Mahommedan influence was seen not only by the personal association of the latter, but by the knots that were used as charms both by some of these societies as well as by individuals. The names and varieties of these societies were numerous. Those nearest to each other were generally on good terms, though distinct; and all could be more or less connected. In various instances the Government could employ these societies to carry out its ends, and by means of methods to which the natives were accustomed could gradually habituate them to British law and order.

M. le Comte Charles de Cardi read a paper on "The natives of the Niger Delta," giving an account of the early navigators who visited Western Africa; of the origin of the Benin people and of many of their customs; of Ju-Juism in the delta, with some description of devil-huts; and concluding with an estimate of the capabilities and future of the West African natives.

Mr. C. H. Read contributed a paper, illustrated by a series of lantern slides lent from the collection of the Anthropological Institute, on "Ancient works of art from Benin city." He pointed out that the position of Benin near the great waterway of the Niger had brought it into contact with influences from the north. It was thus possible that here might be found some relics of the ancient civilisations of the Mediterranean. Relations with Abyssinia were founded on the journey of a Franciscan friar from Benin to Ethiopia in the fourteenth century, and some corroboration of this was found in the Benin tradition that the king was subject to a powerful prince far to the east. In the hope of finding evidence of these traditions in the loot that came from Benin, Mr. Read had made representations to the Government, with the result that a large collection of ancient examples of Benin art had been secured for the British Museum, though it could scarcely be said that they had any direct bearing on the relations of Benin with either the extreme north of Africa or the East. A document of great interest bearing on their origin was a report by Sir Ralph Moor, giving the account of a palaver with the Court historian, three Ju-ju men, the master smith, the master wood-carver, and the master ivory carver, from which it appeared that the white men first came in the time of King Esige, and one of them, named Ahammangiwa, made the plaques and brass-work for the King. Assuming an average reign of twenty to twenty-five years for each of the kings, this would bring the time of Esige to about 300 years ago, a date that would correspond very well with the date of the European costumes shown in the plaques.

Mr. C. W. Hobley sent some vocabularies and illustrative examples of the languages of Kavirondo. Copies of these are to be seen and consulted in the library of the Anthropological Institute.

In the afternoon Prof. Flinders Petrie gave a summary of the principal discoveries during the last five years that had revealed the rise of Egyptian civilisation. Various excavations at Koptos, Naqada, Abydos and Hieraconpolis had discovered remains belonging to the ages before 4000 B.C., which had hitherto been the starting point of known history. Beginning with the Libyan stock, with some Negro mixture, which occupied Egypt in its earliest civilisation, he showed some of the objects he had found at Naqada. These were at first temporarily assigned to a new race; but now they could be safely assigned to the pre-dynastic stock about 5000 B.C., and even earlier. In the graves of this aboriginal race were found bowls of black clay with patterns imprinted upon them. In each of the countries where this type had been found, it was contemporary with the introduction of metals. The proximate date of this was 5000 B.C.—and that accorded very well with the time necessary for arriving at the high culture attained by 1500 B.C. Therefore these discoveries were of great value in giving the relative state of Egyptian civilisation to that of the rest of the world at the introduction of dynastic rule. There was a wide difference between the people of 5000 B.C. and those of 4000 B.C., but no difference between those of the latter period and modern times. This showed that a different race entered the country about that period.

Next came the earliest dynastic remains, *e.g.* the presumed tomb of King Mena, the founder of the dynastic history, of about the date of 4700 B.C., then the remains of other royal tombs found at Abydos belonging to the first three dynasties. The gradual decay of flint working between 4500 B.C. and 1500 B.C., as metals came into use and copper was gradually hardened into bronze, had no parallel in the world. Prof. Petrie showed diagrams and impressions of cylindrical seals as used by the kings of the first three dynasties, also a vase exhibiting the earliest representation of Egyptian mythology and other vases, tablets, and slates showing animals and birds. These finds were very important, as they showed the rise of the art of modelling, and of the Egyptian ideas and appreciation of the forms of animals and of the human body, and proved that Egyptian art reached its high-water mark somewhere before B.C. 4000. Other finds showed the kings in triumph over their enemies, receiving captive kings, opening the public works, or reclaiming the marshes. The handled copper vessels showed the most advanced metal work found of the first three dynasties. The population of the pre-dynastic age was different in type from that of historical times, and in the early monuments the presence of diverse types was very clear. We had at last before us evidence of the close of the period previously considered prehistoric, showing the development of the art, writing, and civilisation of Egypt and the composition of a race which had since maintained its character during 6000 years. Egypt was then an originator in the arts and not a borrower, but ever since then most of the nations of the earth had been borrowers and not originators. Here we were studying the history of a country not borrowing but developing a vast and complex civilisation on its own resources.

Sir John Evans said that the wonderful flint knives must have been the culminating point of an art stretching over a vast series of years. Where was all that civilisation developed? He hoped that the recent conquests in Egypt would materially assist us in investigating that matter.

Mr. Arthur Evans thought a comparison of the pottery of other parts of the Mediterranean basin with that of Egypt helped to bridge the gap which separated early Egypt from the dawn of civilisation in Europe. He considered that Prof. Flinders Petrie would be safe in assigning his discoveries even to an earlier date than he had done.

Prof. Flinders Petrie, in reply, said that he himself thought that he was well within the mark, but he chose the date he had fixed in order to be absolutely safe.

Miss A. Goodrich Freer then read a paper on "The folk-lore of the Outer Hebrides." This folk-lore has a degree of interest which justified the inconvenience attendant on its collection. A peculiar value attaches to the ancient hymns, stories and legends, and to the charms, spells and divinations, because these were more certainly becoming difficult to recover.

On Wednesday, September 14, in the morning, the programme consisted of papers on archæology and folk-lore.

Mr. Sidney Hartland presented the sixth Report of the Committee on the Ethnographical Survey of the United Kingdom, emphasising the fact that, while the whole scheme of the committee's inquiries included a number of subjects, it was not considered necessary for each observer to deal with them all, and that some subjects, such as current traditions and beliefs, and dialects, were more immediately pressing than others.

Mr. A. Bulleid presented the third Report of the Committee on the Lake Village at Glastonbury. Twelve more dwelling mounds have been examined, as well as the ground between and around them, and the southern end of the settlement has now been completely explored, the timber substructure in this locality being in a better state of preservation than in any part hitherto examined. Mounds A, B, C and D showed the gradual growth of the village, easily recognised by the floor of one mound overlapping the floor of the mound immediately contiguous to it, also for the number of bone needles found. Mound E contained the remains of a small furnace of baked clay, fragments of crucibles, and small pieces of bronze. In Mound A A, part of the framework ostensibly of a loom was discovered; evidently discarded before the first dwelling was erected.

Mr. Arthur Evans supplemented this report with a paper on the place of the Glastonbury Lake Village in British archæology. He insisted upon the homogeneous character of the culture here revealed, and showed that it belonged entirely to the pre-Roman period and the first and second centuries B.C. It represented a distinct phase of a form of culture introduced into Britain by the invading Gaulish tribes. The glass-working industry of Glastonbury was probably derived, by the same overland route as various forms of vases, safety-pins, and other relics, from the old Venetian region] where this art flourished already in prehistoric times. The name Glastonbury itself was a translation of the Celtic Ynis-witrin—Glass Island.

Prof. Boyd Dawkins said that the inhabitants of that village had most probably introduced both glass-making and lead-mining. He had no doubt that Mr. Arthur Evans's derivation was correct. Sir John Evans thought that the mere fact of the dwellings being in that unsuitable position pointed to the probability that the constructors were lineally connected with other lake dwellers on the continent of Europe. That the occupation of the village ceased in the first century after Christ seemed probable, because of the general absence of Roman ware.

Prof. W. M. Flinders Petrie then read a paper on traces of primitive *Terramare* settlements in the modern towns of North Italy. He showed that recent clearing at Castellaro di Fontanellato had disclosed the fact that the marsh towns of North Italy in the Bronze age were arranged on a strictly square system of crossing roads, and that this type of town was perpetuated in the regular plan of the camps of the Roman army. On examining the present plans of the cities of Lombardy, the outline of the original square settlements could be plainly traced. Replying to the objection that the existence of square forms of towns did not itself prove that those forms were of pre-Roman date, Prof. Petrie said that that was not really his argument; granting or assuming the pre-Roman date, the square forms of the towns would indicate the presence of *Terramare* settlements.

Mr. P. F. S. Amery then exhibited, with explanatory remarks thereon, a series of lantern slides showing the megalithic monuments of Dartmoor, in anticipation of the Devonshire excursion arranged in connection with the Bristol meeting.

The Report of the Committee on the Excavations at Silchester stated that the area selected for excavation in 1897 included two *insulæ* (XVII. and XVIII.), extending from *insula* III. (which was excavated in 1891) to the south gate, and lying on the west side of the main street through the city from north to south. It is proposed during the current year to excavate the two *insulæ* south of *insulæ* XV. and XVI. (excavated in 1890), and a triangular piece of ground to the south of them, almost as large as a third *insula*. When the examination of this area is completed, considerably more than half the city will have been systematically excavated and planned.

Miss Nina Layard reported the discovery of human skeletons walled up in the remains of the Black Friars' monastery at Ipswich.

Mr. T. W. Shore read a paper on traces of early Kentish migrations. He identified such early Kentish colonies by Jutish or Kentish place-names under their present or more ancient form; by other place-names derived from the Jutish hero Hengest; by survival of gavelkind and customs of land tenure analogous to those of Kent, and of kindred customs.

Papers on the folk-lore of Guernsey, by the late Mrs. Murray-Aynsley, and on myths of insect life, by Mr. S. Clement Southam, were taken as read; and the session closed with a vote of thanks for the use of the Park Place Schoolroom, and with the exhibition in the Committee-room, by Mr. H. Bolton, of human relics from the recently discovered caves at Uphill.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A LETTER written by the Public Orator, Dr. Sandys, thanking Mrs. John Hopkinson and other members of her family for their munificent benefaction of 5000*l*. to the University of Cambridge, to be applied to the building of a memorial of the late Dr. John Hopkinson and Mr. J. G. Hopkinson, was read by Dr. Sandys in the Senate House, and approved by Grace of the Senate, on November 10. It has since been engrossed on parchment and presented to Mrs. Hopkinson.

Science announces that the late Edward Austin, of Boston, has given by his will 1,100,000 dollars for public purposes; 500,000 dollars is left to Harvard University, 400,000 dollars to the Massachusetts Institute of Technology, 30,000 dollars to Radcliffe College, 30,000 dollars to Roanoke College, and 30,000 dollars to the Tuskegee Normal and Industrial School. The income from these large bequests is to be used for scholarships. The sum of 10,000 dollars is also given to the bacteriological laboratory of the Harvard Medical School.

AT a conference on secondary education, convened by the Victoria University, and held on December 3 at Owens College, Manchester, resolutions were passed urging that (1) a Minister of Education of Cabinet rank should represent the Education Department in Parliament. (2) The consultative committee mentioned in Clause 3 of the Bill laid before the House of Lords last session should be obligatory. (3) Immediate provision should be made for the institution of local authorities for secondary education. Another resolution, to the effect that the relations of the proposed Board of Education to the Charity Commissioners should be more clearly defined in the Bill, was adopted.

A COURSE of about thirty-three lectures on "The Morphology and Histology of the Vascular System," commencing on January 11, will be given at University College, London, by the assistant professor, Mr. A. G. Tansley, each lecture to be followed by two hours' practical work or demonstration. An attempt will be made to trace the evolution of the stele of the vasculares through the various stages exhibited by pteridophytes and phanerogams. A special feature of this part of the course will be the inclusion of the important fossil types, many of which throw much light on the course of evolution of the vascular system, and whose anatomy has become fully understood only through the researches of the last few years.

SIR J. GORST, M.P., delivered an address to agriculturists at Cambridge on Saturday afternoon, on "Education in Agricultural Districts." In the course of his remarks, he said that reports showed that the chief reason for the prosperity of agriculture in foreign countries was the education of the people in all technical knowledge pertaining to their industries. If efforts were to be made to raise agricultural education in this country to something like the level of Denmark, France, or Switzerland, they had a very difficult task before them. Elementary education was the bed-rock upon which the whole of the superstructure must be built. It was useless to attempt a national system of technical instruction until there was a sound system of elementary instruction upon which it could be based.

THE Association of American Agricultural Colleges and Experiment Stations recently held a successful meeting at Washington, D.C. The following facts with reference to the Association and its work make a striking testimony of the condition of agricultural education and research in the United States: The institutions represented in this Association employ over 1500 persons in their faculties, who are giving instruction to about 30,000 students. These institutions have over 50,000,000 dollars in permanent endowments, buildings and equipment, and an annual revenue of nearly 6,000,000 dollars, of which more than 2,000,000 dollars is derived from funds granted by the United States. Besides the work of instruction, they are carrying on original research in different directions. This is especially true in many scientific lines relating to agriculture, over a million dollars being spent for this purpose annually. There are now pending in Congress propositions to establish, in connection with these institutions, experiment stations for investigations in mechanical arts and naval engineering, for which some of the colleges already have considerable facilities.

THE Chelsea Physic Garden is in future to be administered in accordance with an extended scheme. The *Pharmaceutical Journal* states that the Apothecaries' Society has decided, owing to considerations of expense, to abandon the management of the garden which, it will be remembered, was founded by Sir Hans Sloane in the early part of the eighteenth century, and was subsequently transferred to that Society in trust. A scheme has accordingly been drawn up for vesting the control in the Trustees of the London Parochial Charities, but it is proposed that the actual management should devolve upon a committee of fifteen members, eight to be nominated by the Trustees, and one each by the Treasury, the Lord President of the Council, the Royal Society, the Technical Education Board,

the Society of Apothecaries and the Royal College of Physicians in turn, the Pharmaceutical Society of Great Britain and the Senate of the University of London. It is intended that the existing garden should be fully maintained, a suite of rooms being provided for lectures and experimental teaching, whilst the Trustees are to be given authority, if they think fit, to erect and fully equip a physiological laboratory.

To carry out the new scheme referred to above, an annual income of eight hundred pounds is to be provided by the Trustees, and it is proposed in addition that the committee shall be furnished with such a capital sum as may be necessary to enable them to enforce the scheme to its full extent. The committee is to appoint a curator for the scientific supervision of the garden, and other members of the staff. Further, the committee will be authorised by the scheme to provide instruction in botany by means of lectures, demonstrations, &c., with special reference to the requirements of elementary education; to arrange for the maintenance of botanical collections of living plants for teaching purposes, and, so far as practicable, for the supply of botanical specimens for the purpose of external instruction. Students of institutions receiving aid from the funds of the City Parochial Foundation are to be eligible for admission without payment of fees; and it is provided that, so long as a yearly payment of not less than one hundred and fifty pounds is made to the Trustees out of the moneys provided by Parliament, students of the Royal College of Science shall also be admitted to the garden without payment, while they, the professors and teachers of the College, shall be entitled to the use of the garden, the botanical collections, and the lecture rooms for such time as may be approved by the Charity Commissioners. It will thus be seen that the scheme is of a far-reaching character, and calculated materially to increase the usefulness of the garden.

SCIENTIFIC SERIALS.

Memoirs of the Kazan Society of Naturalists. Vol. xxx.—On the oro-hydrography of the Nizhne-Isset mining region in Middle Ural, by V. Rozhkoff, with an orographic map in which the plateau character of the region appears very well.—On intra-cellular growths in cancer, by A. Rebrovsky, with a plate. Sporiferous growths were not found in cases unaccompanied by wounds.—On the parisitism of the Rotatoria *Notomatta Wernecki* in the Vaucheria, by W. Rothert, with a plate.—On the geology of the water-parting between the Volga and the Don at Tsaritsyn, by M. Yanischewsky. A large development of old Post-Pliocene alluvial deposits was found.—Water in wells at Kazan, by Prof. Scherbakoff.—On crystal-bearing cells in cork membranes, by W. Rothert. The observations of Zacharias, Cederwall, and Meyer are confirmed by observations on *Agave*, *Fourcroya*, *Drocaena*, and several others.

Vol. xxxi.—On the structure of the membrane of the vessels in plants, by W. Rothert, with a plate. A preliminary report on extensive researches ioto this question.—On the pathological and anatomic changes in organs and tissues resulting in raphania, ergotismus, and similar diseases, by N. Vinogradov, with one coloured plate. A detailed investigation of many cases of these diseases, which often assume in Russia an epidemic character.—On investigations of the soil, made in 1896 by R. Rispolozhensky. Part of a wide system of investigation which is being carried on for many years in Russia.—Chemical and physical researches into the soils of Kazan, by V. Sorokin.—The fauna of the upper parts of the Permo-Carbonic formations on the Kama and Chusovaya rivers, by N. Romanov. Eighty-nine species are described, the following being new: *Aviculopecten Stuckenbergi*, *A. parvulus*, and *Pleurotomaria fluctuosa*. The deposits belong to the Kungur division of Prof. Stuckenberg.

Bollettino della Società Sismologica Italiana, vol. iv., 1898, No. 4.—On the investigation of seismic periodicity by the method of overlapping means, by C. Davison. A description (in English) of a rough method of harmonic analysis suitable for the investigation of the annual and diurnal periodicity of earthquakes, with examples worked out in illustration of the method.—On the increase of activity presented by Vesuvius in the months of April and May, by R. V. Matteucci.—Notices of earthquakes recorded in Italy (September 1897), by G. Agamennone. A long and valuable series of records of three earthquakes, two of which originated at Labuan (Borneo) on September 20 and 21, and the third in the province of Ancona (Italy) on September 21.

Bulletin de la Société des Naturalistes de Moscou, 1897, No. 4. This volume contains one paper, "*De Aphodio scuticolli m. (nigrivitti, Rth.) ejusque cognatis*," in Latin, by A. Semenoff. The remainder is taken up with the proceedings, which contain a number of shorter notes, and the yearly report. During the year 1897 a considerable number of members of the Society, chiefly botanists, explored various parts of Russia.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 17.—"The Electrical Conductivity and Luminosity of Flames containing Vaporised Salts." By Arthur Smithells, H. M. Dawson, and H. A. Wilson. Communicated by Sir H. E. Roscoe, F.R.S.

(1) The authors conclude from their experiments, that the conductivity of vaporised salt is of an electrolytic character, but that there are features connected with it that distinguish it from electrolytic conduction in aqueous solution. Thus Ohm's law is only obeyed within certain limits, and the general relation between current strength and electromotive force can only be represented generally by a more complex expression.

(2) The conductivities of different salts differ greatly, according to the electropositive constituent.

(5) Among different salts of the same metal differences of conductivity appear at the higher concentrations, but at low concentrations equivalent solutions have equal conductivity.

(4) The conductivity of the haloid salts as a group is distinct from that of the oxy salts.

(5) The conductivity of the haloid salts of a metal among themselves increases with the increasing atomic weight of the halogen.

(6) The conductivity of the oxy-salts of a metal is approximately equal, and approaches that of the hydrates.

(7) The more easily oxidisable halogen salts are probably partly converted into oxide in the flame, so that their conductivity is composed of two parts.

(8) The behaviour of the salts in flames supplied with chloroform vapour seems to establish the fact that the conductivity and the colour produced by the salt vapour are not due to a common cause.

The coloration of a flame by an alkali salt does not seem therefore to be connected with the conisation of the salt. It must be attributed to the metal set free by a chemical process. This process consists probably in a reduction effected by the flame gases. An oxy-salt would, generally speaking, form in the first instance an oxide, which would then be reduced. In the case of haloid salts it seems also necessary to suppose that an oxide is intermediately formed, the metal being then liberated by reduction.

Physical Society, December 9.—Mr. Shelford Bidwell, F.R.S., President, in the chair.—Dr. C. Chree read a paper on longitudinal vibrations in solid and hollow cylinders. The ordinary formula for the frequency of longitudinal vibrations refers to an ideal rod of infinitely small section. This formula constitutes a first approximation, according to which the higher notes are exact harmonics of the fundamental note. Prof. Pochhammer, and Lord Rayleigh independently, over twenty years ago, arrived at a corrective term for solid isotropic rods of circular section, according to which the harmonic relation between the notes is no longer exact. During the last twelve years Dr. Chree has devoted several papers to the subject, confirming by independent methods the *results* obtained by Pochhammer and Rayleigh, and arriving at analogous results for other forms of section, and for material symmetrical round an axis but not isotropic. The first part of the present paper develops what appears to be a new method, based on expressions obtaioed some years ago by the author for the mean values of the strains in an elastic solid of any kind or shape, exposed to any system of forces. Besides confirming his previous results, Dr. Chree obtains new results applicable to material neither isotropic nor symmetrical round the axis of the rod. The second part of the paper treats of a hollow circular rod, or tube, of isotropic material. When the walls of the tube are thin, the correction to the ordinary formula is twice as large as for a solid

rod of the same diameter. The different methods all point to the conclusion that the ordinary formula supplies a close approximation to the truth only so long as the greatest diameter of the cross-section is small compared to the nodal interval in the rod.—A paper on the thermal properties of normal pentane, by Mr. J. Rose-Innes and Dr. Sydney Young, was then read. In 1894 the authors investigated the relations between the temperatures, pressures and volumes of isopentane, through a wide range of volume; the results are published in the *Proc. Phys. Soc.*, xiii. pp. 602–657. It is there shown that if a and b are constants depending on the nature of the substance and on the volume, the relation $p=(bT-a)$ at constant volume holds good with but small error from the largest volume (4000 cub. cms. per gramme) to the smallest (1·58 c.c. per g.). In the neighbourhood of the critical volume (4·266 c.c.), and at large and very small volumes, the observed deviations are well within the limits of experimental error, but at intermediate volumes they are somewhat greater. As they exhibit considerable regularity, it is a question whether they could be attributed entirely to errors of experiment. In any case, the above relation may be accepted as closely approximate to the truth. The present paper refers to a similar investigation on pure normal pentane obtained by the fractional distillation of the light distillate from American petroleum. The method employed for this separation is fully described in the *Trans. Chem. Soc.*, vol. lxxi. p. 442, 1897; the vapour pressures, specific volumes as liquid and saturated vapour, and critical constants are given in the same journal, p. 446. With regard to theoretical deductions from the present results, advantage is taken of the fact that a similar set of experiments had already been carried out with isopentane, which is an isomer of normal pentane. It was hoped that light would be thrown on the question of the influence exerted by difference of chemical structure on the thermal properties of a substance. The conclusion arrived at as most probable is that the coefficients of the second power of the density in the expansion of p must be different for the two substances. The slope of the curve obtained by plotting $(av^2)^{-1}$ against $v^{-\frac{1}{2}}$ suggests discontinuity somewhere about vol. 3·4, as with isopentane. Mr. Lehfeldt asked whether the authors had observed any other singularity or discontinuity at vol. 3·4. He also asked whether the authors were satisfied with ordinary squared-paper in plotting their curves. It ought to be possible to design a machine for doing the work mechanically to one-fiftieth of a *m.m.* accuracy. Mr. Appleyard said the fractionating apparatus devised by Dr. Young was a great improvement on older forms; it ensured that there should always be sufficient and yet not too much liquid at each valve-trap. He hoped that details of the tube, in its latest form, would be included in the paper. In the separation of such a mixture as chloroform and alcohol the common method by water-extraction was imperfect; it was not desirable always to convert the mixture wholly into chloroform. Ordinary fractionating tubes yielded an impure distillate in this case. Perhaps the difficulty was inherent for those two liquids. Dr. Young's apparatus would put the question beyond doubt. Dr. Young, in reply, said that the only objection to curve-tracers was their cost. The curves he had obtained from his experimental results were all isothermals: he did not think isobars would indicate anything such as Mr. Lehfeldt had suggested. With regard to such mixtures as chloroform and alcohol, the chances of separation were difficult to predict. A distinction might, however, be drawn between liquids partially miscible, and liquids miscible in all proportions. Hexane (b.p. 69° C.) and benzene (b.p. 80° C.) for instance, were both hydrocarbons miscible in all proportions, and it might be thought possible to separate them by a fractionating apparatus. But experiment shows they cannot so be separated. If alcohol and chloroform should turn out to be miscible in all proportions, the probability was that they could not, effectively, be fractionated; if, on the other hand, they prove to behave like partially miscible liquids, the separation by a fractionating apparatus such as he had described was rendered possible.—The President proposed votes of thanks to the authors, and the meeting adjourned until January 27, 1899.

Chemical Society, December 1.—Prof. Dewar, President in the chair.—The following papers were read:—The oxidation of polyhydric alcohols in presence of iron, by H. J. H. Fenton and H. Jackson. In presence of iron, methylic, ethylic, propylic, isopropylic and amylic alcohols are not oxidised by hydrogen peroxide; but vigorous oxidation of ethylene glycol, glycerol, erythritol, mannitol, dulcitol and sorbitol is effected by hydrogen peroxide in presence of, but not in absence of, ferrous salts.—The occurrence of hyoscyamine in the *Hyoscyamus muticus* of India, by W. R. Dunstan and H. Brown. The stem and leaves of *Hyoscyamus muticus* contain about 0·1 per cent. of hyoscyamine; the alkaloid can be extracted more readily from this plant than from henbane.—The comparative colour of the vapour of iodine in gases at atmospheric pressure and in a vacuum, by J. Dewar. By distilling and condensing iodine on a glass surface at −180° to −190° in vacuum test-tubes or bulbs, transparent films of iodine of varying thicknesses may be obtained. On enclosing pure iodine in half-litre flasks, a visible colour is imparted to the air, carbon dioxide, hydrogen or oxygen with which the flask is filled at ordinary temperatures; if the flask be evacuated, the colour of the atmosphere is markedly less, and this distinction remains even when the flasks are heated side by side on the water-bath.

Paris.

Academy of Sciences, December 5.—M. Wolf in the chair.—Contribution to the theory of the safety bicycle. by M. J. Boussinesq. A mathematical investigation of the equilibrium of the rider.—On the anomalous dispersion and magnetic rotatory power of certain incandescent vapours, by M. Henri Becquerel. In a previous paper the author has explained the unusually great rotatory power observed by MM. Macaluso and Corbino for radiations from sodium vapour in the immediate neighbourhood of absorption bands by regarding the phenomenon as one of abnormal dispersion. In the present paper experimental details are given of a method of making the sodium flame act itself as a prism. The spectrum from an electric arc, which has passed through this flame, shows discontinuities in the neighbourhood of the D-lines. The results form a complete explanation of the results of MM. Macaluso and Corbino, and are in agreement with the theoretical views previously put forward by the author.—On the velocity of sound in air, by M. J. Violle. A discussion of the objections raised by M. Leduc to measurements of the velocity of sound made in the open air. It is shown that the presence of moisture leads to a correction which is smaller than the experimental error of the measurements.—On the synthesis of phenol from acetylene, by M. Berthelot. This synthesis is of interest on account of the comparatively low temperature (200° C.) at which it can be effected. Acetylene is passed into fuming sulphuric acid, the liquid diluted, and the potassium salt prepared of the acid thus formed. This salt, submitted to a potash fusion at 180° to 220° C. for twenty minutes, the mass acidified and distilled; phenol is readily recognisable in the distillate. A repetition of the process upon the residue in the retort yields more phenol.—Action of acetylene upon the metal-ammoniums, by M. Henri Moissan. The metals (sodium, potassium, lithium, and calcium) were dissolved in liquid ammonia at −40° to −80° C., and pure acetylene gas passed in. The residues obtained after evaporation of the excess of liquid ammonia had the compositions, respectively, of $C_2Na_2.C_2H_2$, $C_2K_2.C_2H_2$, $C_2Li_2.C_2H_2.2NH_3$, $C_2Ca, C_2H_2, 4NH_3$; all these compounds dissociate on heating, leaving the corresponding carbides, C_2Na_2, C_2K_2, C_2Li_2, C_2Ca.—The colour of calcium carbide, by M. Henri Moissan. Absolutely pure calcium carbide is transparent and colourless; the presence of a minute trace of iron is sufficient to give it the reddish brown colour of the material obtained by the electric furnace.—On the properties of aluminium, by M. A. Ditte. Aluminium is readily attacked by many chemical reagents, acids, alkalies and salts; but in many cases a protecting layer of gas or oxide is formed, so that little or no action takes place in cases where thermochemical data would lead to the prediction of a very energetic attack. Circumstances which destroy this film, lead to rapid solution of the aluminium.—Histology of the skin, by M. L. Ranvier. A study of the fatty matter of the corneal layer of epidermis in man and other mammals.—The liver as a pigmented organ in the Invertebrates, by MM. A. Dastre and W. Floresco. A comparison of the differences and similarities of the hepatic organs in Vertebrates and Invertebrates.—On the prediction of the occultations of stars by the moon, and on the calculation of terrestrial longitudes by means of occultations, by M. G. Bigourdan.—Numerical results obtained for the latitude of the Observatory of Paris by observations made on the garden meridian circle, by MM. H. Renan, J. Perchot, and W. Ebert.—On the determination of gravity on the summit

of Mont Blanc, at Chamonix and at Meudon, by M. Hansky.—On differential equations of the second order with fixed critical points, by M. Paul Painlevé. —On the singular points of a function defined by a Taylor's Series, by M. Le Roy.—On the reduction of multiple integrals, by M. Ch. J. de la Vallée Poussin.—On a new phenomenon exhibited by light in traversing certain metallic vapours in a magnetic field, by MM. D. Macaluso and M. O. Corbino. A discussion of the theory advanced by M. Henri Becquerel.—Remarks by M. Becquerel on the preceding paper.—Absorption in a magnetic field, by M. A. Cotton.—Comparative study of the Hertzian field in air and in water, by M. Albert Turpain.—The Blondel-Carpentier hysteresimeter and its application to the statical measurement of hysteresis, by M. A. Blondel. The paper is accompanied by diagrams of the apparatus. Measurements made by the ballistic method were in close agreement with the readings of the instrument.—On the transmission of sound by a wire capable of conducting electricity, by M. Dussaud.—Displacement of metals by hydrogen, by M. Albert Colson. Dry phosphate of silver absorbs hydrogen in the dark and at 12° C. with production of free silver and phosphoric acid. This change goes on more rapidly when the temperature is raised. Silver pyrophosphate, sulphate, and oxide behave similarly.—On the combination of acetone with mercuric sulphate, by G. Deniges. The compound formed has a very high molecular weight, and contains only one-seventeenth of its weight of acetone. Hence it is a suitable means of detecting and estimating small quantities of acetone.—Action of hydrocyanic acid upon epichlorhydrin, by M. R. Lespieau.—On the development of the dilator muscle of the pupil in the rabbit, by M. Ed. Grynfellt.—On the digestion of starch in plants, by M. Leclerc du Sablon.—Elective absorption of some mineral elements by plants, by M. E. Demoussy. If nitrates and chlorides are simultaneously at the disposal of a plant, nitric nitrogen is absorbed in preference to chlorine.—Chlorophyll assimilation in terrestrial orchids, and in particular in *Limodorum abortivum*, by M. Ed. Griffon. Terrestrial orchids, considered from the point of view of carbon assimilation, are intermediate between plants such as *Epipactis*, in which carbon is taken from the air, and colourless species like *Neottia* and *Corallorhiza*, which are entirely saprophytic. In *Limodorum*, in spite of its richness in chlorophyll, its respiration of carbon dioxide is always greater than its assimilation.—On the toxic powers of chromium compounds with respect to the higher plants, by M. Henri Coupin.—On a new cupric broth, specially designed to combat the black rot, by M. Joseph Perraud. The addition of colophane imparts to the mixture great adhesive power and resistance to washing off by rain.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 15.

ROYAL SOCIETY, at 4.30.—(1) Application of Liquid Hydrogen to the Production of High Vacua, and their Spectroscopic Examination; (2) The Boiling Point of Liquid Hydrogen under Reduced Pressure: Prof. Dewar, F.R.S.—Ionic Velocities: Prof. O Masson.—Note on the Densities of Atmospheric Nitrogen, Pure Nitrogen, and Argon: Prof. Ramsay, F.R.S.—The Preparation and some of the Properties of Pure Argon: Prof. Ramsay, F.R.S., and Dr. Travers.—Observations on the Anatomy, Physiology, and Degenerations of the Nervous System of the Bird: Prof. Rubert Boyce and Dr. W. B. Warrington.—The Action of Magnetised Electrodes upon Electrical Discharge Phenomena in Rarefied Gases. Preliminary Note: C. E. S. Phillips.—On the Reciprocal Innervation of Antagonistic Muscles. Fifth Note: Prof Sherrington, F.R.S.

LINNEAN SOCIETY, at 8.—Sketch of the Zoology and Botany of the Altai Mountains: H. J. Elwes, F.R.S.—A Description of some Marine and Freshwater Crustacea from Franz Josef Land, collected by W. S. Bruce, of the Jackson-Harmsworth Expedition: Thos. Scott.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.

CHEMICAL SOCIETY, at 8.—The Interaction of Ethylic Sodiomalonate and Mesityl Oxide: Dr. A. W Crossley.—Derivatives of Camphoric Acid. Part III.: Dr. F S. Kipping, F R.S.—Synthesis of $\alpha\beta\beta$ Trimethylglutaric Acid: H. Perkin jun., F.R.S., and Dr. J. F. Thorpe.

FRIDAY, DECEMBER 16.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Kentish Town Widening, Midland Railway: Walter Daniel.

QUEKETT MICROSCOPICAL CLUB, at 8.

TUESDAY, DECEMBER 20.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Paper to be further discussed: The Ventilation of Tunnels and Buildings: Francis Fox.——And, time permitting, Paper to be read with a view to discussion: High-Speed Engines: John Handsley Dales.

WEDNESDAY, DECEMBER 21.

GEOLOGICAL SOCIETY, at 8.—On a Megalosauroid Jaw from Rhætic Beds near Bridgend, Glamorganshire: E. T. Newton, F R.S.—The Torsion-Structure of the Dolomites: Dr M. M Ogilvie (Mrs. Gordon).—The Oceanic Deposits of Trinidad, W I.: Prof. J. B. Harrison and A. J. Jukes-Browne.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—The West Indian Hurricane, September 1898: Captain A. Carpenter, R N.—The Connection between the Winter Temperature and the Height of the Barometer in North-Western Europe: W. H. Dines.

ROYAL MICROSCOPICAL SOCIETY, at 7.30.—Exhibition of Binocular Microscopes.

THURSDAY, DECEMBER 22.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Telegraphy by Magnetic Induction: S. Evershed.—The Discussion on Dr. Lodge's Paper (Improvements in Magnetic Space Telegraphy, and on Mr. Evershed's Paper, will be opened by Dr. Fleming and Mr. Preece, with Experimental Demonstrations.

BOOKS and SERIALS RECEIVED.

CONTENTS.

THURSDAY, DECEMBER 22, 1898.

GEGENBAUR'S COMPARATIVE ANATOMY OF THE VERTEBRATA.

Vergleichende Anatomie der Wirbelthiere: mit Berücksichtigung der Wirbellosen. Von Carl Gegenbaur. Erster Band. Einleitung, Integument, Skeletsystem, Muskelsystem, Nervensystem und Sinnesorgane. Mit 619 Zum. Theil farbigen Figuren im Text. Pp. xiv + 978. (Leipzig: Wilhelm Engelmann, 1898.)

THE first volume of the long-expected work by the master has appeared. By placing the study of anatomy upon the basis of evolution he had become the founder of modern comparative anatomy, and he has raised the building to a great extent by his own hands, supported by a school of disciples, ever increasing through his stimulating and correcting influence.

No wonder that for years expectation has been keen about this book, which must necessarily be the crowning of his life's work. The present volume, besides an introduction, deals with the tegumentary, skeletal, muscular and nervous systems, and the sense organs.

It would be a hopeless attempt here to give anything ike an adequate *résumé* of the nearly 1000 pages of this first volume. Only some of the salient features can be touched upon. The plan is grand; the execution can be fully appreciated only by those who have made comparative anatomy their special study, because the treatment frequently soars to such heights that the enormous amount of detail which is marshalled in the book, almost seems to disappear before the generalising ideas into which the facts have been welded and condensed. This is especially the case with the introductory chapters prefacing, or the summarising retrospects following upon, the principal chapters. But this does not make easy reading, and some of the sentences, although containing beautifully conceived ideas, are so idiomatic and so terse as to appear almost oracular. For instance, he discusses the development of the bird's wing, how the quills growing upon the patagium, and gaining preponderance over it, have become the functional wing surface, while the patagium itself loses its importance and becomes correspondingly reduced. The result of this contemplation is summed up thus: "Das Product tritt functionell an die Stelle des Bodens, auf dem es entstand."

The general introduction alone, taking up the first seventy pages, is an ideal treatise of morphology, dealing with such fundamental questions as adaptation, correlation, differentiation, inheritance, ontogeny with reference to phylogeny, value and meaning of the germinal layers, &c.

A characteristic feature, going like a red thread through the whole book, is the animosity against ontogenetic research so far as that is in the hands of those whom our author speaks of as embryographers. According to him the ontogenetic record is of no use unless it is in full concord with the results arrived at by the comparative anatomical method, and not many opportunities are missed which afford a stab at ontogeny where this has failed to elucidate a certain problem. The embryographer will, therefore, feel inclined to smile when he comes across the not unfrequent passages where, palæontology remaining mute and comparative anatomy revealing nothing, the problem in question is summarily dismissed as one fit for the ontogenetic method.

Another leading feature is the striving to derive any given organ from something else, from another one previously existing, instead of being satisfied with its origin *in situ*. Of course this is the true scientific, evolutionary method, and it is the very one by which Gegenbaur's works have become epoch-making; but occasionally the idea seems to be a little overdone, and it is then not always easy to reconcile the various arguments with each other. For instance, in the discussion of great importance, pp. 590-592, which runs approximately as follows:

It is more reasonable to derive cartilaginous parts from other existing cartilage, although their ontogeny may show them to make their appearance where they are wanted in the organism. Thus it is, for instance, preferable to assume the derivation of the Cyclostomes' gill-basket from the cranial cartilage, instead of believing that this basket-work has originated *in situ*. "It is (p. 590) very probable that the whole of the cartilaginous skeleton took its origin from the perichordal cartilage."

All this is certainly very satisfactory and uniform, but as the author himself has pointed out on p. 200, it is becoming more and more plausible that the original home of cartilage was in the integument, in the ectoderm. Its appearance in the perichordal neighbourhood would in this case be a secondary feature, owing to chondroid infiltration into the connective tissue. But if this is so, then there would be nothing unreasonable in the assumption that the gill-basket of the Lamprey had received its cartilage *in situ*. We do not want to press this derivation, but it seems unfair categorically to ask (p. 591):

"What business has a cell, or even a group of cells, to transform itself here or there into cartilage? One or a few cells, even when they become cartilaginous, do not yet possess a supporting function; at any rate the causal momentum of this transformation would remain obscure, as the result of the transformation cannot at the same time be its cause."

This certainly sounds very uncompromising, but the mystery of the origin of the cartilage is not solved by deriving it from other cartilage. The same consideration applies to the derivation of bone, and our author makes the following statement, p. 594:

"Indem wir das knöcherne Skelet nicht mehr ausschliess lich vom Bindegewebe ableiten, durch an sich unverstaendliche, weil in ihren Causalmomenten nicht darzulegenden Veraenderung en jenes Gewebe an den betreffenden Orten entstanden unsvorstellen, sondern den wesentlichsten Antheil bei seiner Entstehung in den Osteoblasten finden, werden die ersten Anfaenge der Hautskeletbildung (Selachier) mit den hoechst verwickelten Zustaenden des Skeletes der Wirbelthiere aufs innigste verknüpft."

The sentence just quoted, rather typical of the style, defies direct translation, but its sense may perhaps be rendered as follows: By referring the most essential share in the formation of the bony skeleton to the osteoblasts, we are enabled to connect intimately the first beginnings of the dermal skeletal formation (of Selachians) with the highly differentiated condition of the skeleton of the higher Vertebrata. We no longer derive

the bony skeleton exclusively from the connective tissue, and we no longer imagine that these tissues arose *in situ*, owing to changes which, as their causes cannot be explained, are by themselves not understandable.

In connection with the above consideration may be mentioned the following important views (p. 152): Although treated as an hypothesis, it appears likely that enamel, dentine, bone substance, are all of ectodermal origin, and the same is probably the case with cartilage. And p. 200: There are reasons for assuming, although not yet absolutely sure, that the whole mass of the placoid scale, including the bone, arises from the ectoderm. Anyhow, all the hard structures, and all their bony formations are derived from the integument. In the higher creatures the bone-forming material is already mixed up with the mesoderm, and our author thinks that the perichondrium has received its bone-forming elements likewise from the integument.[1] Some skleroblasts are certainly identical with osteoblasts, and these latter become eventually bone-corpuscles.

Anyhow, at last, the bugbear of the fundamental difference between tegumentary (so-called secondary, in reality primary) and chondral bone, and that between endo- and ecto-chondral bone, is recanted. Gegenbaur himself had introduced these differences, which have been used for the last thirty years as an all-powerful conjuring formula. He has laid the ghost originally raised by himself; laid perhaps too effectively, as the old terms could easily be made to receive a corrected meaning, in harmony with the old well-meant distinction, if—instead of primary and secondary bones in the old sense—we put primary and secondary elements of the primordial skeleton.

The author (p. 186) is in favour of the connection of the so-called notochord (which he would rather not straightway call a notochord) of Cephalodiscus, Rhabdopleura and Enteropneusta, with that of the Tunicates. The lucid treatment of this important structure may be used as an example of how the conditions prevailing among Invertebrata can be made to throw light upon the more complicated Vertebrata. He argues, namely, as follows:

"The origin of the chorda from entoderm, from the gut-wall, is phylogenetically not understandable. Such a string of cells must originally have had another function than that of support. It is therefore reasonable to derive the chorda from some gut-diverticulum, such as actually does exist at the very place whence phylogenetically the chorda must have begun; the diverticulum, as well as the chorda arising, moreover, at the spot where ento- and ecto-derm meet. And although such diverticula no longer exist in Tunicates, their ancestors must necessarily have possessed them, because some of the recent Tunicates have a chorda. Moreover, the occurrence of such diverticula in several otherwise divergent forms, as, for instance, Cephalodiscus and Rhabdopleura, indicate a former, more widespread existence."

All this is very satisfactory, but how does it fit in with what we read further on about the brain and the spinal cord?

[1] It is difficult to see how this tegumentary origin of cartilage (for which also see p. 152) can be reconciled with the statement made on p. 241—"An additional argument against the exclusive origin of cartilage from mesoderm is the transformation of chordal into cartilage cells"—even if this so-called chordal cartilage had not been shown by Zykoff and others to be an erroneously interpreted observation.

Gegenbaur, namely, has always held that the brain is the older, and the spinal cord the newer formation. Considering the importance of this question for the origin of the Vertebrata from Invertebrata, we turn eagerly to what he has now to say on this point. But instead of receiving comfort, we are led into a maze. See for this the following three statements:

(P. 724.) The phylogenetic value of the ontogenetic mode of origin of the spinal cord, namely, as a further continuation, or budding, from the brain, can be contested. Because such a mode of formation would presuppose a condition in which the spinal cord had preserved its ectodermal position in the ancestors of the Acrania. Only the epichordal nerve-string of the Tunicates represents a sort of early stage of the spinal cord, but in reality it is not yet a spinal cord.

(P. 725.) Exclusively ontogenetic treatment of this question shows that the spinal cord is phyletically produced by a successive budding from the archencephalon. But if this were really so, then the otherwise so well-founded connection with the Tunicates would disappear. . . .

On p. 779 the author holds that the mode of formation of the cord in Petromyzon and in Teleostei, as a solid string with subsequent appearance of a central canal, is more primitive than the early formation of a semi-canal of the medullary plate as observed in all the other Vertebrata.

These three statements are not easily reconciled, and that ontogeny supports the budding mode is an assertion at least surprising. But behold, on p. 718 and p. 719, concerning Tunicates, we are told that:

"Die Medullarplatte senkt sich in die Tiefe, besonders hinten, wodurch eine Taschenform entsteht. Die nach vorn sich weit oeffnende, hinten geschlossene Tasche erstreckt sich immer weiter nach hinten, indess ihre aeussere Oeffnung sich verengt, und als Neuroporus weiter besteht."

At first sight the reader will think that *nach hinten* is a *lapsus calami*, instead of *nach vorn*, but this is not the case. The sentence also reads as if neuropore and blastopore were the same, but a few lines further on we are categorically informed that certain other features, for instance the neurenteric canal, "are cenogenetic, and have to be passed over." In fact the author translates into growth backwards what ontogeny clearly shows to be the opposite, namely, the closing in of the canal from the blastopore forwards. Consequently the secondary nature of the spinal cord, as a budding from the brain, receives no support from ontogeny, while according to the author himself it can be contested upon phylogenetic grounds!

For the rest we cannot do more than single out a few paragraphs as samples, be they typical illustrations of the masterly treatment of the whole work, or be they falling short of, or running contrary to, our expectations.

The author emphasises the great difference between Sauropsida and Mammalia, and as we read further through the book all the differences are made much of, until the only group worthy of possible ancestral relationship are the Amphibia, notably Anura. This old view has been revived, and it is difficult to say if this unfortunate notion of Amphibian descent "mit Umgehung der

Sauropsiden" is a conclusion arrived at from structural grounds, or if it in turn is responsible for the acceptance of certain morphological conclusions. One, out of many, is the sanction given to the startling attempt made by his prosector, to derive the hair from something older than Sauropsidan structures, namely, from certain degenerating sense organs of Amphibia. A very able criticism of this hypothesis has, by the way, been given by Keibel in Merkel and Bonnet's periodical. The same idea of relationship underlies the treatment of the skin-glands, the skeleton of the limbs, the homologies of the ear-bones, &c.

The paragraphs dealing with the vertebral column are not a success; the question is left where Klaatsch left it in 1895, and that does not go beyond the cartilaginous fishes; the rest is written on the old futile lines. Nor can much praise be bestowed upon the treatment of the ribs, in which—instead of his old well supported teaching—a compromise has been made adopting the view of the existence of upper and lower ribs, mixing up thereby true ribs and other parts, which, although likewise differentiations of ventral arches, are not, nor ever were ribs. At the same time there is a tenacious pleading for the correctness of his original view. One of the causes of this uncertain state is the wholesale adoption of the results arrived at by one of his assistants.

Perhaps all through the book an easily understood, but nevertheless somewhat undue preference is given to papers published in the *Morphologische Jahrbuch*. Herewith is connected a peculiar treatment of the literature, which shows many deficiencies, more due to design than to accident, because the author says pointedly that he has restricted himself to the most important writings. Anyhow, this may be said in explanation: The MS. seems to have been practically finished several years ago, and little notice has been taken of what has been published since, except the work done by those with whom the author has been more or less in contact, bringing thereby some additions down to even last year's publications.

The genesis of the Chelonian carapace is a most suggestive chapter, but difficult reading, especially since, a page or two further on, the right of existence of an alternative view is conceded, namely, that neural and costal plates may after all be of dermal origin. Dermochelys, in support of the leading view in the text, is pronounced to be a low, most primitive form, but a little further on the mosaic shield of this turtle is confessed to be in a state of retrogression.

The visceral, branchial skeleton of the Cyclostomes (p. 415) is of ectodermal origin. "It must, however, have been derived from the cranial cartilage, for we cannot possibly side with the old teleological notion that this cartilage arises in the ectoderm *in situ* of the future branchial skeleton, and develops itself into the necessary branchial arches. A small interbranchial bit of cartilarge, consisting perhaps of a few cells only, would be of no use, and, moreover, why should such isolated bits of cartilage cells turn up there? But the assumption that the branchial apparatus arises as little processes of the already existing cranium, gives them at once a supporting function." Then follows a beautiful, lucid description of the branchial skeleton of the Gnathostomata, the whole long chapter, from Elasmobranchs to the highest Mammalia, with all the marvellous modifications, ultimately into hyoid, epiglottic and laryngeal apparatus being welded into an harmonious illustration of onward evolution.

On p. 460, in winding up with a fascinating *résumé* concerning the emancipation of the head from the rest of the body, the author takes the opportunity of severely reproaching the embryologists.

"Comparison teaches us that the visceral arches of the Amniota are derived from branchial arches; the descriptive method reveals only the differences, and takes no stock of the fact that these gill-less visceral arches were once gill-bearing arches. This knowledge is the result of the comparative method and of conclusions based upon these facts, conclusions which stand in contradiction to ontogenetic experience. But while this has not prevented any one from acknowledging the homologies of visceral and branchial arches, the same kind of conclusion when applied to the cranium [namely, to its metameric origin] meets with objections."

But was this outburst necessary? Who, having followed the last ten years of extremely active, and chiefly embryological research, does now object to the metameric composition of the head?

Curiously enough, his famous theory of the origin of the limbs and their girdles from visceral arches is only sketched in the very outlines. He devotes but a few very critical remarks to the important support, which his theory has gained from ontogenetic research, and how far ontogeny can be expected to yield results. This is surprising, because nobody, unless he has studied the whole question and the literature attentively, will be convinced by the perusal of the few pages 461–466. We had the right to expect a critical marshalling of the whole apparatus of comparative anatomy, with the numerous points in favour, drawn from the skeletal, muscular, and nervous systems, and refutation of the almost equally numerous mistaken contrary comments. The derivation and evolution of the free limb is, however, done splendidly, although we miss a discussion of the axis of the dactyloid limb. The author himself says, in the preface, that he could not treat everything with equal fulness, but there are not a few points on which we should have liked this very authority's opinion. We look, however, in vain for more than a passing remark under epitrichium, subnotochordal rod, proatlas, pisiform bone, os acetabuli, &c. He holds that there were never more than five fingers "unless a creature can be shown which normally possessed more." All the so-called vestiges of additional fingers and toes are discarded summarily; but might not Kükenthal's discovery of excalation of fingers in the Cetacea have been given at least passing consideration?

More than 100 pages are devoted to the muscular system, making quite a new feature in a text-book, considering how scantily it had been treated hitherto from a general point of view. It is the first successful attempt to bring the mass of accumulated observations into one frame, beginning with the invertebrate conditions as the fundamental starting-point, and then paying especial attention to the muscles of the head, and to the derivation of those of the limb from the truncal system. The nerve-supply is of course taken as the guide, while the almost

endless modifications are in many cases followed back to more primitive conditions. It is scarcely necessary to say that Gegenbaur himself initiated this treatment, culminating in the elaborate researches of Fuerbringer and Ruge.

The grouping of the cranial nerves is also quite new, but any attempt to arrange the cranial and cranio-spinal nerves without reference to their origin in the central ganglionic columns, must needs lead to failure ; and that is the case here. The metamerism of the cranial nerves implies a problem which is not only morphological but essentially physiological, and here was a chance for the morphologist to join hands with his physiological brother, instead of the usual complaint about the abstaining attitude of the latter, and absolutely ignoring his histological and experimental work.

Whilst discussing the modifications of the visceral arches, concerning the formation and the homologies of the ear ossicles (this vexed question has entered a new phase, far from being at rest), he makes the following remark : "Although none of these cases [certain reptilian modifications] are immediate preparations for the mammalian condition, they nevertheless appear as attempts towards this new modification." This is by no means the only instance of his speaking of attempts, or preparations, precocious and aborted, anyhow unsuccessful in one group, foreshadowing arrangements in others ; *e.g.* bipedal gait of Dinosaurs with reference to birds.

The last 127 pages are devoted to the sense organs. After a masterly general introduction follows a most interesting chapter on the organs of the "Hautsinn," taste, ear, eye, nose, each with an invertebrate prolegomenon, full of descriptive detail and all turned into a broadly conceived, well composed and carefully finished picture.

There is no book like this one on comparative anatomy. In broadness of plan, depth of conception, and critical execution it cannot be surpassed. Instead of being a fund of detailed facts, as some of its predecessors, it is a mine of wealth of most suggestive ideas.

If we have in some respects found fault with the book, the explanation suggests itself that the architect and master-builder has too trustingly taken over his material as sound and flawless from the bricklayers, carpenters, and other helpers. But the partial disappointment may also perhaps be a fault of our own, of those who expected too much from their old master, whom they look up to with a gratitude and reverence bordering on veneration.

H. GADOW.

ELEMENTARY QUANTITATIVE ANALYSIS.

An Introduction to Practical Quantitative Analysis. By H. P. Highton, M.A. Pp. 211. (London: Rivingtons, 1898.)

MR. HIGHTON appears to belong to the growing class of teachers of chemistry who believe that the practical work of beginners should be of a quantitative character. Qualitative analysis may, it is true, be made an excellent drill ; it attracts most young students, and its practice, if it be properly taught, undoubtedly promotes the formation of orderly habits, develops the powers of observation, and encourages the use of the reasoning faculties. But if it be ill taught, few studies are of less value.

It has been pointed out again and again that when the classes are large and the teachers few, when the available time for study is brief, and if the students come unprovided with a fair elementary knowledge of chemistry qualitative analysis is sadly apt to degenerate into the futile pursuit known as test-tubing. Moreover, this branch of work does not offer a very good selection of clear and simple illustrations of the fundamental laws of chemistry ; and it is these, after all, which we especially want to impress upon the minds of those young students who learn chemistry for the sake of its educational effect, and not, at first, in order to become chemists.

These and other similar considerations, as we all know, have led many schoolmasters to postpone qualitative work to a later stage than that at which it was formerly commenced, especially in schools where it is the practice to turn whole classes of young boys into the laboratory, instead of making them listen to lectures of a more or less formal and didactic character in the lecture-room, according to the older practice. It is natural, therefore, that of late years many attempts should have been made to produce a book suited to the needs of the juniors of to-day, as the "Small Roscoe" and "Little Miller" provided for those of earlier generations, in the times when the number of school laboratories might have been counted on the fingers of a single hand. And although nothing seems yet to have been produced which exactly supplies the existing need, several of the new books have been helpful and suggestive.

Mr. Highton's little book certainly takes rank with this latter class. It contains eighty-six carefully selected experiments, which have all been performed by boys in the Rugby Laboratory. These eighty-six experiments cover a fairly wide field, they are clearly described and illustrated by a number of helpful diagrams, they include several exercises in those parts of physics which are of the most direct importance to students of elementary chemistry, and several of them are quite easy ; but their character as a whole suggests that they will be found to be more suitable for the senior boys, than for beginners in the lower forms. For the former they ought undoubtedly to be useful, in spite of a certain want of suggestiveness, in the arrangement of the book, which seems likely to impair the educational value of the course, by leading the student to look upon the experiments as mere bits of manipulative and mental gymnastic, and to overlook their relation to the science as a whole. This is a defect, however, which may be remedied by the teacher, by means of verbal discussions of the results obtained, and by rearranging the order of the experiments to suit his methods of teaching.

Whether Mr. Highton's book will soon find a sufficient field of usefulness, we cannot say. We hope it may, but we fear it may not ; for, alas ! too many teachers are still very much at the mercy of the examiner, and qualitative analysis still rules supreme in many of the leading examinations at which public school boys compete. Doubtless it is very difficult to make fundamental changes in an examination syllabus, and it must be admitted that the Examining Boards would

provoke howls of disapproval if, in the year 1899, they should suddenly ordain the complete abolition of qualitative analysis. But it is a question whether the time has not now come for a forward movement in this matter.

We will conclude with a suggestion. Is there any reason why those who control "certificate examinations," "army examinations," "scholarship examinations," and the like, should not, on and after some reasonably early date, permit candidates in chemistry to choose between qualitative and quantitative practical work? Such an ordinance would herald a new era of progress in the chemistry teaching of our schools. Nor would the change be so difficult to carry out as might, at first sight, seem probable, for scholarship examiners at the Universities have long since shown us how to examine boys in quantitative analysis. Indeed, had they not unfortunately made the initial mistake of requiring a knowledge of quantitative work without definitely reducing the range of the qualitative previously required, the University Examiners would long since have solved the whole problem. Even as it is, some good has been done—for a start has been made. But in the interests of sound teaching it is vitally important that this mistake should not be repeated, and that those who are responsible for these matters should remember that the time which has been found to be insufficient to afford a sound training in qualitative analysis cannot possibly be sufficient for both qualitative and quantitative work, especially if inorganic preparations are also to be made by the students as they should be. W. A. S.

OUR BOOK SHELF.

The Illustrated Annual of Microscopy. Pp. 164. (London: Percy Lund, Humphries, and Co., Ltd., 1898.)

THE first number of this publication is a very creditable production, from whatever point of view it may be regarded. It is written primarily for the amateur, although some of the articles included could be read with interest by any microscopist, for they indicate the work that has been undertaken and carried out during the year. Perhaps, however, it is in this very direction that the book is deficient, as in some of the articles, instead of treating only those parts of the subject which are of recent interest, a large amount of matter is included that can be found in any good work on microscopy. It might safely be assumed that those who are sufficiently interested in the subject will have the necessary knowledge to enable them to understand the points under discussion without this preliminary instruction. This fault, if it may be called so, is perhaps almost inseparable from the first number of a work of this kind; but no doubt in future numbers there will be less difficulty in attaining the object the publishers state they have in view.

Of the papers calling for special mention, those on bacteriology are all deserving of notice, not the least interesting to the amateur being that by Rev. W. Spiers on "Amateur Bacteriology," in which various simple devices are described, enabling those who have no special apparatus to do a considerable amount of bacteriological work. This is all the more important, as it is thought by many that the study of bacteria is limited to those who have the resources of a bacteriological laboratory at their disposal, whereas there is a considerable field of work open to any one who has a microscope, without entailing any but the most modest expenditure. A paper on "The Diphtheria Group of Bacilli" deals with an important subject, and one to which considerable attention has been given of late. The paper on "Multiple Colour Illumination," by J. Rheinberg, describes a simple method of effectively exhibiting microscopic objects which, of themselves, do not possess any colour contrast. The microscope and its optical parts comes in for a good share of attention. There is an article on "The Microscope in 1897," by Dr. Henri van Heurch, the mention of whose name is sufficient guarantee of its interest. Mr. Edmund J. Spitta treats of "Achromatics *v.* Apochromatics," and endeavours to show, by a series of photo-micrographs, the immense superiority of the latter. Nearly all branches of microscopy have been touched upon, and into whatever channel the interest of the reader may be directed he is almost sure to find something of interest. Altogether, the book is admirably produced; the illustrations, which are nearly all reproductions from photographs, being of the highest class, and comparing favourably with any of the kind that have been published. It is to be hoped that the publishers will find it possible to continue the issue of this annual, as it cannot fail to be of interest and value to microscopists.

J. E. B.

Wild Animals in Captivity. By A. D. Bartlett; edited by E. Bartlett. Pp. viii + 373, illustrated. (London: Chapman and Hall, Ltd., 1898.)

THE late Mr. Bartlett had such an extensive and almost unrivalled practical acquaintanceship with animals in menageries, that the publication of the notes kept by him during a long life might naturally be expected to be an event of more than usual interest. But, although there is much to attract general attention, and not a little worthy the notice of the practical zoologist in the present volume, we cannot help rising from its perusal with a certain feeling of disappointment. It appears, indeed, that a very large proportion of the notes that have any real value have been published elsewhere. And although this is a matter of little or no moment when the subject is good and attractive, it is essential that such republished notes should be well arranged and edited. In our own opinion efficient editorship is sadly wanting in this instance. The various notes and papers are far from being well arranged; and there is a considerable amount of repetition, as well as much irrelevant "padding," which might advantageously have been omitted. As a glaring instance of the former fault, the reader may be referred to pp. 164 and 165, where he will find precisely the same anecdote, with identical dates, repeated under two distinct headings; the only difference being that one account is more detailed than the other.

The diction, too, in many places, if not actually unungrammatical, is decidedly inelegant; and the need of competent scientific editorship is strikingly apparent in the concluding chapter of the book, which treats of the food of animals in captivity, and is one of the most valuable in the whole volume. Misprints, also, are by no means absent; the substitution of the word "joints" for "points" rendering a sentence on p. 27 almost unintelligible.

Neither do we consider the preliminary biographical notice of a decidedly remarkable man all that it might be; and, while the rest of the volume might be much abbreviated with advantage, this part would well bear expansion.

With regard to the merits of the book, all readers will admire the many anecdotes of the striking personal courage and devotion displayed by the late author in his dealings with the animals under his charge. There is much, too, in regard to their general habits in confinement which cannot fail to be of importance to all

connected with menageries; while many of such notes are valuable clues to their mode of life in a state of nature.

A subject in which Mr. Bartlett took especial interest is that of hybrids; and to him, amongst others, belongs the credit of showing that sterility is by no means such a general attribute of the products of crossing as has been supposed. The chapter on hybridisation is, therefore, worthy of the best attention of naturalists.

R. L.

Wild Life at Home. How to Study and Photograph it. By R. Kearton, F.Z.S. Pp. xv + 188. (London: Cassell and Co., Ltd., 1898.)

THIS delightful book, by the author of the well-known "With Nature and a Camera," deserves a wide popularity. It should be of value in spreading the love of the "bloodless and harmless sport," of which Mr. Kearton writes so enthusiastically. The beautifully reproduced photographs are in themselves more than justification for the addition of the volume to the numerous bird-books already in existence, and the careful and practical instructions which are given to the reader, to enable him to secure similar trophies to those illustrated, will tempt many nature-lovers to follow in the footsteps of Mr. Kearton and his brother, Mr. C. Kearton, who has provided the photographs. In addition to illustrations and notes on birds, the volume contains chapters, with striking pictures, on mammals, insects, and other forms of life.

A Pocket Dictionary of Electrical Words, Terms and Phrases. By Edwin J. Houston, Ph.D. Pp. iv + 945. (London: Swan Sonnenschein and Co., 1898.)

THE growth of the terminology of electrical science has been so rapid, that the new terms and phrases coined since the publication of the last edition of the author's larger dictionary, exceed in number those which were originally in use. This necessitated a re-casting of the previous work; and to avoid the production of a cumbersome volume, the greatest attention has been paid to conciseness of expression, with the result that this handy little epitome has been produced. It is even now too large for a pocket dictionary, and it would perhaps have been better to have reduced the bulk by omitting many of the words which are familiar enough to need no explanation.

Ricettario Industriale. By I. Ghersi. Pp. 562. (Milan: Ulrico Hoepli, 1899.)

This book, which is one of the latest additions to the well-known series of "Manuali Hoepli," contains some 940 recipes used in the arts. Among these there are many which will be of value to scientific workers. Of the subjects treated, the following are a few of the more important: Coloration, plating and cleaning of metals; paper, celluloid, cements, ebonite, matches, preservation of fruit, flowers, eggs, &c.; bleaching, ink, oils, perfumes, soap, varnishes, ivory, glass, wine. So far as we are able to judge, the recipes given are practical and up to date.

Deutscher Botaniker-Kalender fur 1899. By P. Sydow. Pp. 198. (Berlin: Gebruder Borntraeger.)

THE dates of the births or deaths of distinguished botanists, mostly natives of Germany, are indicated in this pocket diary for 1899. In addition, the rules of nomenclature followed by officers in the Imperial botanical gardens and museums of Berlin are given; and there are lists of works on cryptogamic plants, of botanical gardens in Germany and elsewhere, botanical and natural history museums and collections, and an alphabetical list of the officers in botanical museums and great herbariums.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Anthropological Expedition to Torres Straits.

THE members of the Cambridge Anthropological Expedition to Torres Straits have now completed their investigations in the Straits. Dr. Rivers and Mr. Wilkin have left for England, while the other members of the expedition have proceeded to Borneo to study the anthropology of the Baram district of Sarawak. The health of the party has been excellent.

The natives of Murray Island were studied with most detail, as, owing to their isolation, they have been less modified by contact with alien races. Some of the party stayed about four months on the island, while others had only a couple of months, owing to a trip having been made to the mainland of New Guinea.

The New Guinea contingent visited the coast tribes between Kerepunu and the Mekeo district, and several excursions were made for short distances inland. There was not enough time spent at any spot for a thorough investigation of the natives, but a considerable amount of information was obtained in most of the branches of anthropology with which the expedition is concerned, which will prove of value for purposes of comparison.

The researches on the Murray islanders were fairly thorough, and will form a basis for comparison with the other islanders and allied peoples. Over a month was spent in Mabuiag (Jervis Island) by all the party, with the exception of Messrs. Myers and MacDougall, who had previously started for Borneo. Although the time spent in Mabuiag was short, a satisfactory amount of work was accomplished owing to the conditions being favourable. Observations were also made on several other islands in Torres Straits and in Kiwai, which is situated in the mouth of the Fly River.

A large number of photographs have been taken, and considerable collections have been made, which are now on their way to Cambridge.

A. C. HADDON.

Thursday Island, November 7.

Transference of Heat in Cooled Metals.

SEVERAL observers[1] have noticed a rise of temperature at the cooler end of a bar of metal when the hot end was suddenly cooled. As this would be a most surprising effect, and as Johns Hopkins University has been mentioned in connection with the subject, Dr. H. A. Rowland has requested me to examine the matter.

Iron and steel bars of about one-half inch diameter were used, and iron-copper thermo-electric couples were soldered to the cooler end and the side. A reflecting galvanometer was used that gave a deflection of 1 mm. per 0°·05 C. The end of the bar was heated by a Bunsen compound burner, or in a muffle furnace with a blast lamp. The hot end of the bar was cooled either with blocks of ice or by plunging into ice water.

After errors, due to jarring the galvanometer, and to changes in the magnetic field of the galvanometer, caused by motion of the bar, had been eliminated, even under the most trying conditions no effect was observed. The temperature of the cooler portion of the bar did not increase when the hot end was suddenly quenched.

The most severe test imposed included the sudden quenching in ice water of the end of the bar, three inches of which was above the red heat. The thermo-couple then was only nine inches from the glowing end of the bar.

The galvanometer, of course, showed the usual slow change of temperature due to conduction. There was then a comparatively long time after quenching before any change of temperature was indicated, and then the change was only a reduction of temperature.

CARL KINSLEY.

Johns Hopkins University Physical Laboratory,
Baltimore, U.S.A., December 9.

[1] NATURE June [illegible], 1898 (observed by M. Bourget in Paris [illegible]); September 1, 1898 (observed by Mr. Bartlett in Cavendish Laboratory, 1899); October [illegible], [illegible] (observed by Mr. Stone in Johns Hopkins Laboratory, 18[illegible]).

Where do we stand in Brückner's Weather-cycle?

THE problem of future weather is one which has a fascination for many. Our present inability to get beyond (or much beyond) the daily forecast, may well, at times, seem a reproach, considering the immense amount of industry that has been given to weather studies. Where is the professional meteorologist in this country (we vainly ask), who, on the basis of some cycle, or proved recurrence, or other facts, will tell us, even in the most general way, what the coming years have in store for us?

Yet the time may not be so very distant, I think, when science will be able to say, *Nous avons changé tout cela.* The evidence of cycles is growing; and their character is being more exactly fixed. An attentive reader of that excellent record, the *Meteorologische Zeitschrift*, may observe, now and again, a feeler (so to speak) put forth into the obscure; a serious attempt to extend the range of prevision, a suggestion, by some well equipped mind, as to the course of weather in coming years or seasons. Have we not in such the hopeful beginnings (hopeful even in case of failure) of a new and difficult art?

There are two weather-cycles, which have lately been (shall I say?) knocking for admittance; that of 11 years, and that of 35 years. It is well to bear in mind that these are not mutually exclusive. They may be found to usefully supplement and help each other.

Brückner's views as to the recurrence, at intervals of about 35 years, of cold and wet periods, alternating with warm and dry ones, seem to have hardly received, as yet, in this country, the attention which they deserve. They are destined, I believe, to have a large influence on future thought about such matters. It may be useful to ask how our London weather is related to this 35 years' cycle; and I propose to do so here from the standpoint of barometric pressure.

The method adopted is this: Each month, in a long series of years (from 1786), is first characterised as + or −, according as its pressure has been above or below the average. (Tables by Eaton and Glaisher have been used for the purpose.) Then the plus months in each year are counted, and the series of numbers so obtained is smoothed by additions of 10 (*i.e.* adding the first 10, then from the 2nd to the 11th, the 3rd to the 12th, and so on, each sum being put down in the *fifth* place). This gives us the dotted curve A in the diagram, in which may be seen, underlying minor variations, a succession of long waves. The general outline of these waves may be more clearly brought out by a further smoothing process (continuous curve).[1]

In order to clear understanding of this curve A, consider, for a moment, its lowest point, that for 1842; this means, that, in the 10 years, 1838–47, there were 50 months of + barometric pressure, out of 120. Similarly, the highest point (that for 1891), means that in the 10 years 1887–96, there were 67 months of + pressure out of 120.

Note the intervals between minima of this curve A. From 1813 to 1842, 29 years; 1842 to 1876 (34 years). Or, taking the twice-smoothed curve, we get 35 and 32 years. On the other hand, the two completed waves are approximately bisected by the vertical lines for 1830 and 1860 (interval 30 years).

At the top of the diagram are two linear series representing, the one, Brückner's warm and cold, the other, his dry and wet, periods (warm and dry, continuous lines, cold and wet, dotted lines). These two series, for temperature and rainfall, are not, it will be seen, exactly coterminous; the latter tend to lag somewhat on the former. Brückner's general figures may be given, so far as they here concern us.[2]

Temperature.		Rainfall.	
Warm ...	1791–1805 (15 yrs.)	Dry ...	1781–1805 (25 yrs.)
Cold ...	1806–1820 (15 „)	Wet ...	1806–1825 (20 „)
Warm ...	1821–1835 (15 „)	Dry ...	1826–1840 (15 „)
Cold ...	1836–1850 (15 „)	Wet ...	1841–1855 (15 „)
Warm ...	1851–1870 (20 „)	Dry ...	1856–1870 (15 „)
Cold ...	1871–1885 (15 „)	Wet ..	1871–1885 (15 „)

Now, it will be noticed that our barometer curve A at its lowest points is generally about the middle of the cold periods, while the middle of the waves is about the middle of the warm periods. Also, that the parts of the twice-smoothed curve above the average line are about coterminous with warm periods; while the parts below the average line are in general coterminous with cold periods.

[1] Here the sum of 10 items is put down in the *sixth* place.

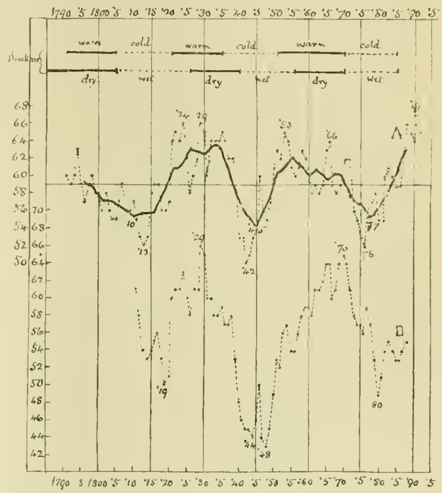
[2] *Klimaschwankungen*, p. 236.

It is surprising, I think, that an agreement so considerable can be brought out by a method so rough.

Do not these facts throw some light on the future? An interval of 35 years from the last minimum, 1876, brings us to 1911, about which time (perhaps a little earlier) we might fairly look for another minimum, the middle of another cold and wet period. At present we are still, apparently, in the warm and dry period commencing about 1886, and probably near the end of it, as (say) 15 years from 1885 brings us to the end of the century. We next enter (by programme!) on another time of cold and wet, with preponderance of low barometers. Thus our curve A should be turning down soon towards its next minimum (situated somewhere between 1906 and 1911).

The rainfall aspect of the current warm and dry period may be put thus: Of the fifteen years, 1883–97, twelve have been dry, and only three wet. 1882 seems to mark the end of a long time of preponderance of wet years.

The curve B is one for Paris, made out in the same way as A (the data, however, extending only to 1893). It shows much the same kind of fluctuation. One curious feature is a lag in the three minima behind those of the London curve.



Regarding barometric pressure in these regions, Brückner considers that in a dry period there is a deepening of the usual cyclone in the North Atlantic (on an annual average), and an intensifying of the ridge of high pressure reaching from the Azores to the interior of Russia, especially in Central Europe; also a general increase of amplitude in the yearly variation (*Klimaschw.*, p. 217). In wet periods, the pressure differences (both from place to place and from season to season) are lessened.

There can be little doubt that this cycle of Brückner's touches life at many points, and that a promising field of study is thus opened up. Take health for example. Brückner himself shows how the mortality from typhus at Bâle has varied with the cycle (being worst in the dry periods). In a recent valuable work on epidemic diphtheria, Dr. Newsholme correlates the mortality from that disease in England with the thirty-five years' cycle, showing that a succession of dry years afford the most favourable conditions for growth of the disease.

ALEX. B. MACDOWALL.

Soakage into Glazed Porcelain.

I MIX salt with water for occasional gargling, and keep it in a porcelain pot with a lid. Some weeks ago I began to use for the purpose a small well-glazed pot, in which cold cream had been bought a long time since. It was thoroughly washed by a

careful servant, and the salt put into it. However, after a few weeks the salt became so strongly impregnated with the odour of rancid grease that it was not fit to be used, and I threw it away. The pot was washed a second time with scrupulous care: it seemed to me quite pure and free from odour: a new supply of salt was put into it, and now for the second time the salt has began to smell intolerably rancid. The interest of this is two-fold. First, it shows how large an amount of impurity is able to penetrate glazed porcelain, as photographers know to their cost; and secondly, it proves the possibility of concentrating odour. An imperceptible discharge from the porcelain was accumulated and stored in the salt until, when the lid was removed, it was found to be overpoweringly strong. The scent may therefore be said to have been *magnified* by these means, as much as a sound is magnified by an ear-trumpet, or a visible object by a lens. F. G.

The Twelfth Movement of the Earth.

UNDER the above heading a short article appears in the *Bulletin de la Soc. Astronom. de France*, October 1898, p. 449, which on account of its interest and of its brevity, as well as its geological significance, is well worth citation, although the matter of it has already been brought before the public by other *Journals* and *Proceedings* of learned bodies.

"The planet which we inhabit has been known by astronomers to be subject to eleven different movements.

(1) Its diurnal rotation around its axis in 23h. 56m.

(2) Its annual revolution round the sun in 356¼ days.

(3) The precession of the equinoxes in 25·765 years.

(4) The monthly movement of the earth about the centre of gravity of the earth-moon couple.

(5) The nutation caused by the attraction of the moon in 18½ years.

(6) The secular variation of the obliquity of the ecliptic.

(7) The secular variation of the eccentricity of the terrestrial orbit.

(8) The displacement of the line of apsides in 21·000 years.

(9) The perturbations caused by the constantly changing attractions of the planets.

(10) The displacement of the centre of gravity of the solar system round which the earth annually turns, which centre depends on the variable position of the planets.

(11) The general translation of the solar system in the direction of the constellation Hercules.

A twelfth movement, that of the terrestrial pole to the extent of 15m. to 17m. per year, which gives rise to a slight variation of latitudes for all countries, is at present the object of assiduous verifications in a certain number of observatories.

Mr. Albrecht has traced out the path followed by the pole about its mean position from month to month, according to the observations of latitude made since January 1, 1890, to June 1, 1897. This slight displacement is due more especially (surtout) to a variation of equilibrium produced by the movements of the atmosphere of the ocean."

It appears singular that this movement of the pole (and consequent variation of latitude) thus clearly determined to be taking place, has not led to any appreciations as to its possible and probable significance in geology. Amongst the many causes advanced to account for the derangements of land and ocean, and consequent changes of climate at various geological periods, has been a supposed displacement of the axis of the earth, which astronomers have been unwilling to admit as having taken place to any notable extent, and which up to the present it was not possible to prove as having really ever existed. Sir Arch. Geikie, in his "Text-book of Geology" (1885), p. 15, discusses the question sufficiently fully, and arrives at the conclusion (p. 17): "Under the most favourable conditions, therefore, the possible amount of deviation of the pole from its first position would appear to have been too small to have seriously influenced the climates of the globe within geological history."

Secular contraction is admitted as a consequence of the slow cooling of the earth, but the rate at which it acts, or its estimation as a force, is hardly attainable. That it may be, and is frequently a cause of earthquake action is admitted. Hence, considering it as a force acting at all parts of the earth's surface with greater or less energy, it is presumable that it is maximum in certain places, and may be so at points in the vicinity of the equator. Its energy may, indeed, here in places, have reached the point, from time to time, of balancing the centrifugal force proper to these places; and in this case it is evident that the ground in such places might be considered as being in unstable equilibrium, and liable to elevation or depression on the occurrence of very slight differences between the two forces in question arising from one cause or another. Now, under such conditions of equilibrium, it is just possible that a very slight variation of intensity of the centrifugal force at the place considered, could give rise to a derangement of the earth's surface such as would be attributed to an earthquake. This variation in the intensity of the centrifugal force might be the result of the movement of the polar axis, and possibly of a very slight movement such as recently observed. But if it be admitted that this movement is continuous, and if it be supposed that it may have been much more intense and much more frequent in former times, it is evident that it may have been a potent agent in bringing about alterations in the relative distribution of land and water in the zone of the equator, and it is reasonable to examine the actual state of this zone for some evidence of such former movements of the polar axis. Now, the equatorial zone lying between 10° to 15° north and south of the equator, is markedly characterised by the predominance of the ocean surface. The equatorial line only traversing land in Africa and South America, Borneo and Sumatra over a total length of about 90°, the remaining 276° of its extent lying on the Pacific, Atlantic and Indian Oceans. The localities where it traverses the land surface are remarkable in respect to their level as regards the sea. Thus the African part of the belt covers a large extent of the watershed valley of the Congo River, and the Victoria Nyanza basin. In a quite recent article in the *Scientific American Supplement* (Sept. 24, 1898, p 19008), the basin of the Congo "has (it is said) been compared by geologists to the dried up bed of an interior sea." In South America the southern portion of the zone represents the watershed valley of the Amazon, that is, a low-lying tract of land. The course of the zone where it traverses the Indian Ocean and the islands of Borneo, Sumatra, and Celebes, is over one of the most disturbed portions of the earth's surface, that is, where alterations of level, with accompanying seismic and volcanic phenomena, have been frequent and almost continuous. Furthermore, one of the results of a change in the position of the polar axis and variations of the intensities of the centrifugal force on the equatorial zone would be, that for points diametrically opposed, the decrease of centrifugal force at one point would necessarily imply an increase of the force at the opposite point, so that if subsidence took place in the one, elevation should be the result in the other, so that wherever the equator traverses land (representing elevation) it should be found traversing ocean (or low land) at the opposite end of the diameter corresponding to this elevated land surface. This practically holds good, since to the African belt is antipodal, a certain extent of the Pacific, while to the South American belt corresponds diametrically the portion of the Indian Ocean occupied by the islands of Sumatra, Borneo and the Celebes, so markedly characterised by the evidences of former and present seismic and volcanic actions. There is, therefore, some probability that in the present arrangement of land and water in the equatorial zone, there may be the traces of former changes of the polar axis. It is well to bear in mind, as regards these small movements of the axis frequently recurring, if not continuously, and giving rise consequently to small but repeated changes in the relative intensities of secular contraction and centrifugal force, that they may really be most potent agents of change, and that therefore, however small, they acquire great significance if found to be recurrent and tending to repeat themselves at more or less regular intervals, and intervals much shorter than those usually assigned to geological phenomena. J. P. O'REILLY.

The Geminid Meteors

WILL you allow me to supplement the observations of the Geminids recorded in the first paragraph of your "Astronomical Column" in NATURE of December 19, p. 157, by mentioning some of my own? They may be interesting as showing the continuance of the shower, as I was unable to begin to keep watch until 12h. 30m. on the 12th. Twenty-seven meteors which appeared in the south and south-east were charted between that hour and 14h. 45m., when clouds finally covered that part of the sky. Of these, sixteen were from one or other of three radiants in Gemini, the most brilliant occurring at 12h. 42m. (= 1st magnitude), at 13h. 35m. (= magnitude 1½), at 14h. 16m. (= 1st magnitude), and at 14h. 23½m. (= Jupiter in bright-

ness). It will be seen, therefore, that with regard to frequency of meteors this later portion of the shower was not to be compared with that witnessed before midnight. Twelve meteors, including one of the first magnitude and two even brighter, were mapped between 11h. 30m. and 13h. on the night of the 9th; four of these were Geminids.

Slug following a Closed Trail.

MY attention was drawn a few days ago to a brown slug, about 2½ inches long, which had made for itself a closed iridescent track on the concrete flooring of a conservatory. I could not find at what point it had got on to the curve, which ran at one end into a damp part of the concrete, but, in four hours from the time I first saw the slug, it had made three complete circuits and two-thirds of a fourth, always keeping the whole of its body on the trail. The latter, of a uniform breadth of 3/16 inch, varied considerably in curvature, but nowhere presented any very sharp corners, and measured, roughly, forty inches round. Though the rate of progression was sufficiently slow, the slug rested on the track for seven hours, after which, thinking it dead, I touched it and found it had not quite dried up. Indeed, without elongating its body, it began to move and laboriously shifted its position by about an inch. There it remained (the time being then 10 p.m.), waiting, perhaps, for the influence of a more humid atmosphere, for morning found it moist and healthy, breakfasting more than a yard from the near and damp end of the track, which it must have reached by completing the fourth circuit, as there was no trail other than the closed one alluded to. If slugs are in the habit of following old trails, it does not appear that the present specimen had any previous experience of a re-entrant path, but that it depended solely on ocular intelligence of the path in advance.

VINCENT DANIEL.

Animals Feeding on Poisonous Plants as Food.

APROPOS of the various instances quoted of animals feeding on poisonous plants, it may be of interest to mention that in this part of India (the North-west Provinces), goats frequently eat, without any ill effect, the leaves and green stems of the "Akaúa" or "Madar" (*Asclepias* or *Calotropis gigantea*), the milky juice of which is an acrid poison for human beings, and is frequently used as such in infanticide cases.

CHAS. A. SILBERRAD.

Muttra, India, November 18.

THE FUMIGATION OF TREES.[1]

THE San José Scale was first discovered by Prof. J. H. Comstock, near San José, California, in 1879, and was named by him *Aspidiotus perniciosus.* It has been found in various parts of the world, and its original habitat has not yet been ascertained with certainty, but is conjectured to be Japan. In 1893 it was first discovered in the Eastern States, having been introduced about six years before with some infested plum-trees from California, in the attempt to obtain an improved plum which should be proof against the attacks of the plum-weevil; but this laudable object proved the means of introducing a much worse pest into the Eastern States. According to the pamphlet before us, it has now been introduced into no less than thirty-three States, besides Canada and British Columbia, chiefly from the centre of infection in New Jersey. The State of Maryland is badly infested, large orchards of plum, pear, peach, cherry, &c., having been almost entirely destroyed by it in some localities. The insect attacks trees and plants in a similar manner to other *Coccidae*, attacking a great variety of plants, and spreading over leaves, trunk, branches, and fruit indiscriminately. The effects of various remedies are discussed by Prof. Johnson, spraying with whale-oil soap, and fumigating with hydrocyanic acid gas, appearing to be the most satisfactory and efficacious remedies.

FIG. 1.—Placing a tent in position over a plum-tree.

[1] "Report on the San José Scale in Maryland, and Remedies for its Suppression and Control." By W. G. Johnson, A.M., Entomologist. (*Bulletin* No. 57 of the Maryland Agricultural Experiment Station, College Park, MD., August 1898.)

The accompanying illustrations, selected from those in the Report, illustrate the mode of applying the latter remedy.

We may add that other countries have become alarmed at the ravages of the San José Scale in America; and in Germany, in particular, it is not only absolutely forbidden to import any living plants of any kind from America, but even from any other country, without a satisfactory declaration that they are not of American origin.

FIG. 2.—Experimenting with hydrocyanic gas in a block of 2500 Bartlett pear-trees infested with San José Scale.

CURIOSITIES OF ORCHID BREEDING.

A FEW years ago the raising of hybrid orchids was entirely in the hands of a few English experts, but quite recently it has been taken up with great success by many growers of these rare and beautiful plants, not only in England, but also on the continent and in America.

Consequently orchid hybrids have become very numerous, while new ones are constantly being brought to light. Up to the year 1860, we find but four flowered hybrids recorded, raised from distinct crosses: during the thirty years following the numbers gradually increased, until in 1890 there were about 200 enumerated. But it is in the present decade that the most rapid strides have been made, the numbers having increased by leaps and bounds until at the present time there are on record no less than 800 orchid hybrids, raised by hand from distinct crosses. These have all flowered in gardens, and have been duly described or recorded in various journals. And when we remember that many of these 800 crosses have been repeated in the same garden, and in other gardens, and that many individual plants may have been obtained from each capsule, we can form an idea of the large numbers of hybrid orchids that have been raised by hand.

Primary Hybrids.

Of the 800 hybrids from distinct crosses, now on record, some 500 are primary hybrids, *i.e.* hybrids of the first generation between two different species. A careful examination of these primary hybrids shows that, as a rule, they are fairly intermediate between their parents, partaking of the characters of both, and at the same time perfectly distinct from either. The latter fact is most remarkable, and at once serves to distinguish primary hybrids clearly from all other hybrids. For example, *Cypripedium* × *Leeanum* is a typical primary hybrid, and has perhaps been raised more frequently and in larger numbers than any other orchid hybrid. It was obtained originally by crossing *C. insigne* (Wallich), ♀, with *C. Spicerianum* (Rchb. f.), ♂, both well marked and distinct species. The hybrid is fairly intermediate both in its outward characters and in its inner structure (see Prof. Macfarlane on "Minute Structure of Plant Hybrids," *Trans. Roy. Soc. Edin.*, 1891, xxvii. p. 245), and although it has innumerable minor and individual varieties, yet it is always perfectly distinct from both of its parents.

Nor has any intrinsic difference been observed in the reciprocal cross, the same forms appearing equally in the obverse and reverse crosses. Often many varieties are obtained from the same capsule, differing slightly in colour, form and size, but all are specifically *C.* × *Leeanum*, and cannot be mistaken for anything else. As it is with *C.* × *Leeanum* so it is with other primary orchid hybrids, so far as experiments have been made. In short, we find that primary hybrids are, as a rule, so intermediate between their parent species, and so com-

paratively uniform in character, that they are specifically distinct from both parents.

Generic Hybrids.

Of the 500 primary hybrids on record, about 100 are generic hybrids, *i.e.* the parents belonging to different genera. In this respect alone these hybrids are interesting, though no doubt the systematic botanist views them with mixed feelings. It is not so long since generic hybrids were looked upon as anomalies, some of the older naturalists even regarding them as impossible, and forthwith proceeded to beg the whole question by classing those genera which were fertile with one another as species of one. Orchid growers, at all events, have almost ceased to regard generic hybrids with curiosity, familiarity with them having bred a certain amount of indifference.

A list of the generic hybrids on record up to the end of 1897, together with a diagram showing how twenty-six different genera have been linked together by artificial hybridisation, has been prepared by the writer and was published in the *Journal* of the Royal Horticultural Society (vol. xxi., April 1898), and to which those interested in the details of generic orchid hybrids may be referred.

Generally speaking, primary generic hybrids follow the rule of specific hybrids in bearing the intermediate characters of their parents, with a narrow range of variation.

But there are a few remarkable exceptions to this rule.

(1) *Epiphronitis* × *Veitchii*, a hybrid out of *Sophronitis grandiflora* (Lindl.) by *Epidendrum radicans* (Pav.).

(2) *Epi-Cattleya* × *matutina*, a hybrid out of *Cattleya Bowringiana* (Veitch) by *Epidendrum radicans* (Pav.)

(3) *Epi-Laelia* × *radico-purpurata*, a hybrid out of *Laelia purpurata* (Lindl.) by *Epidendrum radicans* (Pav.).

(4) *Epi-Laelia* × *Charlesworthii*, a hybrid out of *Laelia cinnabarina* (Lindl.) by *Epidendrum radicans* (Pav.).

These four generic hybrids are very curious indeed, inasmuch as all agree in reproducing the generic characters only of the pollen parent Epidendrum, without the slightest trace of the peculiar structure of the seed-parents, Sophronitis, Cattleya and Laelia. Yet in minor characters, in colour, form and size, the four hybrids distinctly differ from one another and from their Epidendrum parent.

A close examination reveals the fact that these minor differences correspond with the peculiar differences in the parentage, thus showing that the crosses have really been effected: yet at the same time it must be candidly admitted that did we not know the parentage, we could never have determined it, so overwhelming is the influence of the predominant partner *Epidendrum radicans*. It will, no doubt, be observed that *E. radicans* is the pollen parent in each of the above cases. Curiously enough, when this reed-like *E. radicans* is crossed with the pseudo-bulbous *E. vitellinum* (Lindl.), ♀, a similar result is obtained, the offspring *E.* × *radico-vitellinum* being scarcely distinguishable from the reed-like *E. radicans*. Again, when the reed-like *E.* × *O'Brienianum* —itself a hybrid out of *E. evectum* (Hook. f.) by *E. radicans*—is crossed with the pseudo-bulbous *E. vitellinum*, ♀, a similar result is obtained, the offspring being reed-like in habit as in the pollen parent. Yet when the reed-like *E. radicans* is crossed with other reed-like species of Epidendrum. and again when the pseudo-bulbous species of Epidendrum are crossed with species of Laelia, in every case normal hybrids are produced intermediate between their parents.

Though we cannot pretend to unravel this tangled skein, yet, so far as experiments have been made, it seems quite clear that (1) the species of Cattleya, Laelia, Sophronitis, and the pseudo-bulbous species of Epidendrum, when intercrossed, produce normal hybrids intermediate in character.

(2) The same result is obtained when the reed-like species of Epidendrum are united with one another.

(3) But when the reed-like species of Epidendrum are united with the pseudo-bulbous species of Epidendrum, or with species of Cattleya, Laelia and Sophronitis, abnormal hybrids are produced, having the essential characters of the reed-like Epidendra. From these facts it might easily be argued that a reed-like Epidendrum was the ancestor not only of the pseudo-bulbous Epidendra, but also of the more highly specialised genera Cattleya, Laelia and Sophronitis. In that case the pseudo-bulbous Epidendra would form an interesting connecting link between the lowly reed-like Epidendra and the gorgeous aristocratic Cattleya and Laelia.

Prepotent Generic Crosses.

Perhaps the strangest curiosity in the history of orchid hybridisation is the remarkable prepotency of the genus Zygopetalum over the three genera Odontoglossum, Oncidium and Lycaste, so far as experiments have been made. *Zygopetalum Mackayi* (Hooker) has been crossed with four distinct species of Odontoglossum, viz. *O. Pescatorei* (Linden), *O. crispum* (Lindl.), *O. grande* (Lindl.) and *O. bictonense* (Lindl.), also with one species of Oncidium, *O. unguiculatum*, and one species of Lycaste, *L. Skinneri* (Lindl.), by more than one hybridist, and the result has always been the same, namely *Zygopetalum Mackayi* pure and simple, without a trace of the peculiar structure of the pollen parent in any case. This result is very perplexing and exceedingly difficult to account for. I have made careful inquiries into the details of all these cases, and have satisfied myself that accidental self-fertilisation is out of the question, the pollen of the mother parent having been carefully removed in every case previous to pollination. Parthenogenesis, too, is evidently a broken reed to lean upon, for the seedlings from the same seed-pod differed among themselves in colour and other minor characters, which would hardly have been the case had they arisen from parthenogenetic seed-buds. Neither is *Z. Mackayi* naturally prepotent over other species when crossed, there being at least three cases to the contrary. Nor is the genus Zygopetalum naturally prepotent over other genera, as two distinct and intermediate hybrids between Zygopetalum and Colax testify. As in the case of the Epidendrum crosses, mentioned above, it may be suggested that Zygopetalum is the ancestral genus of Odontoglossum, Oncidium and Lycaste, and that the characters of the ancestral genus remain latent in the more recent genera, with the result that when the latter are crossed with the former, the mixing of the germ-plasms causes these original characters to dominate, the outcome being a reversion to the ancestral genus Zygopetalum.

A rather interesting fact has come to light which certainly lends colour to the above speculation:—The seedling Odontoglossums, raised in the gardens of Baron Rothschild, of Paris, during the first eighteen months of their growth, are said to have resembled Zygopetalum more than they did Odontoglossum. This coincides with the established fact that living beings tend to resemble their ancestors in the early stages of their development. However, for the present we must suspend our judgment, and wait patiently for further facts: it is to be hoped that future experiments will throw more light upon these curious generic crosses.

Another curious fact in connection with generic crosses may perhaps be of interest, and that is the remarkable crosses between the East Indian species of Cypripedium and the South American species; these two sections of the old genus Cypripedium have recently been raised to generic rank, under the names of Paphiopedium and Phragmipedium respectively, by Mr. R. A. Rolfe, of Kew,

and seem to form two distinct and natural groups. Hybrids between these two new genera are peculiarly interesting, inasmuch as the former has a one-celled ovary, while the latter has a three-celled one, showing that this condition is no barrier to fertilisation. More than twelve distinct crosses between different species of these two genera are on record, and many plants have been raised, but so far all resolutely refuse to flower, notwithstanding the many inducements that have been put in their way, and many of them are now large vigorous plants, long past the usual flowering age. One plant of these crosses is recorded to have flowered in the United States, but as it flowered exactly the same as the mother plant in genus, species and variety, one cannot be quite sure that the cross was really effected.

Many of the remaining plants (the writer has several in his collection) are distinctly intermediate in their foliage and habit of growth, and clearly bear the stamp of their recorded origin.

Secondary and Tertiary Hybrids.

Of the 800 distinct crosses mentioned in the foregoing, some 270 are secondary hybrids, *i.e.* hybrids of the second generation, one or both parents being a primary hybrid; while thirty are tertiary hybrids, *i.e.* hybrids of the third generation, one of the parents, at least, being a secondary hybrid. So far no hybrid orchids are recorded to have flowered beyond the third generation, but perhaps it may not be premature to mention that unflowered hybrids of the fourth generation are known to be in existence. The writer has in his collection six hybrids of the fourth generation, five years old, all raised from the same capsule, and which contain in their pedigree five distinct species and three distinct hybrids. So that in the near future there will be ample material in this direction at the disposal of the student of heredity; with this distinct advantage, that orchids being individually valuable, their pedigree is carefully and systematically recorded, which unfortunately is more than one can say of the great majority of garden hybrids.

A careful examination of secondary hybrids, shows them to be very different from primary hybrids in their range of variation. As we have already seen, primary hybrids are comparatively uniform in their characters; so much so that, as a rule, they are quite distinct from their parents. On the other hand, secondary hybrids have a much wider range of variation, often approaching either parent, and sometimes even reverting wholly to one or the other. For instance, to take the simplest form of a secondary hybrid, *i.e.* a hybrid crossed with one of its parent species. We find that the offspring, as a rule, are very variable, a few reverting to the parent species and a few to the parent hybrid; but the great majority are intermediate forms approaching either parent, the whole forming a series of links between one parent and the other. In short, we find that secondary hybrids have a far wider range of variation than have primary hybrids.

Natural Hybrids.

The existence of natural hybrids was formerly thought by some naturalists to be highly improbable, if not actually impossible. But now, when absolute facsimiles of supposed natural hybrids have been raised by hand in gardens, from the same two species among which they naturally grow, they can no longer be regarded as pious speculations, but are indeed accomplished facts. The number of proved natural hybrids in orchids alone is now very considerable, with the result that many intermediate and doubtful forms, hitherto classed as distinct species, are now placed in their proper position as natural hybrids. Mr. R. A. Rolfe, of Kew, has done yeoman service in reducing the chaos of natural hybrid orchids to something like order. And so it has come to pass that artificial hybridisation, which it was supposed would lead systematic botany into the direst confusion, by the irony of fate, seems destined to be the only trustworthy means of saving systematic botany from its own confusion; and the systematist, however orthodox he may be, can no longer afford to ignore artificial hybrids.

Fertility of Hybrids.

The question of the fertility of hybrids is a highly interesting one, and especially important to the student of evolution; and I venture to think that recent experiments in orchid hybridisation have added considerably to our knowledge of the subject.

One of the principal objections to Darwin's theory of the origin of species was the supposed general sterility of hybrids.

Darwin fully appreciated this difficulty, and, after a careful and most elaborate survey of the whole question of hybridism, came to the following conclusions:—"First crosses between forms sufficiently distinct to be ranked as species, and their hybrids are very generally, but not universally sterile. . . . The sterility is of all degrees" ("Origin of Species," 6th ed., p. 262). Again:—"The sterility of distinct species, when first united, and that of their hybrid offspring, graduates by an almost infinite number of steps from zero (when the ovule is never impregnated, and a seed capsule is never formed) up to complete fertility. . . . This high degree of fertility is, however, rare ("Animals and Plants," 2nd ed., vol. ii. p. 163). Some fifteen years later, Dr. Alfred Russel Wallace took up a somewhat similar but more definite position. He writes:—"One of the greatest, perhaps we may say the greatest, of all the difficulties in the way of accepting the theory of natural selection as a complete explanation of the origin of species, has been the remarkable difference between varieties and species in respect of fertility when crossed. Generally speaking, it may be said that the varieties of any one species, however different they may be in external appearance, are perfectly fertile when crossed, and their mongrel offspring are equally fertile when bred among themselves; while distinct species, on the other hand, however closely they may resemble each other externally, are usually infertile when crossed, and their hybrid offspring absolutely sterile" ("Darwinism," 1890, p. 152). Since that time, hundreds of hybrid orchids have been raised in gardens; as we have already seen, there are now on record some 500 distinct primary hybrids raised from distinct species, also some 300 secondary and tertiary hybrids from distinct crosses, raised from parents themselves hybrids.

In the face of these facts, therefore, we can hardly maintain that "distinct species . . . are usually infertile when crossed," and still less can we assert that "their hybrid offspring are absolutely sterile." As it is with orchids, so it is with other garden plants that have been hybridised, *e.g.* roses, rhododendrons, dahlias, chrysanthemums, carnations, begonias, pansies, &c.: the wonderful forms seen in gardens at the present day are all hybrids of many generations, being the known product of more than one species; and these are all fertile in the production of seeds. Darwin seemed to attach much importance to the different degrees of fertility in hybrids ranging from complete fertility down to absolute sterility. At present we have no means of ascertaining the relative fertility of hybrid orchids with that of ordinary species, owing partly to the fact that very few crosses have been made in gardens between varieties of the same species, and partly to the fact that many thousands of seeds are contained in one capsule, being practically innumerable. But through the kindness of Mr. Reginald Young, of Liverpool (an enthusiastic connoisseur in Cypripediums) the writer has been able to work out certain statistics

bearing on the question of the comparative fertility of hybrids (see *Journ. Roy. Hort. Soc.*, vol. xxi., April 1898).

The voluminous records in Mr. Young's stud-book cover a period of about five years, and were specially selected by the writer on account of the reputation of the breeder as a careful observer and a precise recorder. Out of the 577 crosses made by Mr. Young among thirty distinct species and fifty-three distinct hybrids of the new genus Paphiopedium, no less than 78·3 per cent. proved fertile, *i.e.* produced good seeds.

Of these, the crosses between distinct species only, 95·2 per cent. were fertile, while of the crosses in which a hybrid was concerned in the parentage 71·8 per cent. proved fertile.

This seems to show that crosses between distinct species are almost if not quite as fertile as crosses between varieties of the same species (taking the latter at complete fertility, *i.e.* 100 per cent.); while crosses with hybrids, though fertile to a high degree, are yet rather less fertile than crosses between species. A further analysis of the figures shows that while hybrids crossed with pollen of pure species give 89·5 per cent. fertile, yet pure species crossed with pollen of hybrids give but 56·7 per cent. fertile. This points to the conclusion that the slight decline in the fertility of hybrids is due in a large measure to the loss of power in the pollen of hybrids.

Why the male element in hybrids should be so much less potent than the female element I cannot pretend to say, but I venture to think that the matter is worthy of consideration as a possible factor in the evolution of species.

Evolution of Species by Natural Hybridisation.

The experimental demonstration of natural hybrids shows clearly that intercrossing between different species is carried on in a state of nature, to a far greater extent than was formerly supposed; and the comparative fertility of these natural hybrids would be of vital importance to them in their struggle for life.

If, as seems highly probable from the above experiments with orchids, it is the pollen only of hybrids that is impaired, and the capacity of the hybrid to bear seed crossed with the pollen of pure species remains practically unimpaired, it is quite clear that the natural hybrid has a part to play in the evolution of new species.

As we have already seen, hybridisation tends to increase variation especially beyond the first generation, and, naturally, the more variable the offspring the better fitted would they be to adapt themselves to changed conditions of life.

If the circumstances changed rapidly and considerably, the variable offspring of the hybrids would stand a better chance in the struggle for life than the more uniform offspring of the parent species, which were themselves specially adapted to the old conditions. In this way, as conditions changed, new species would be evolved more fitted to the new conditions of life than the old species, which they would gradually replace, and I venture to suggest that natural hybridisation is the most rapid of nature's means towards that end.

C. C. HURST.

THE MEETINGS OF THE BRITISH AND FRENCH ASSOCIATIONS IN 1899.

THE meeting of the British Association next year, as we have already announced, will be held at Dover contemporaneously with the meeting of the Association Française at Boulogne, in order that the two bodies may interchange visits. It has been arranged that the visitors from France shall cross over to Dover on Saturday, September 16, and that the return visit of the members of our Association shall take place on the following Thursday. The arrangements on both sides of the Channel, for the reception of the visitors, are not yet completed; but we understand that while the members of the British Association are at Boulogne, the interesting ceremony of inaugurating a statue of our poet Campbell will take place; and that, at Dover, Dr. Charles Richet, the distinguished professor of physiology in the University of Paris (Faculté de Médecine) has consented to deliver one of the evening discourses. Dr. Richet's interesting reply to the official request, which was sent to him through Dr. Michael Foster, the President-elect, is as follows:

Cher maître et collègue,—Je suis trop honoré par la demande que vous me faites pour ne pas accepter immédiatement et sans réserves. Je ne sais pas encore le sujet que je prendrai; nous avons le temps d'en parler.

Si j'accepte ainsi avec joie, c'est que je considère comme vous les dissentiments qui ont séparé et qui séparent nos deux pays, faits pour s'entendre et pour s'aimer, comme absurdes et même criminels. Alors, dans la faible mesure de mes forces, je ferai tout ce qui est en mon pouvoir pour dissiper ces malentendus, et tacher d'apaiser ces haines.

Paris, Décembre 9. CHARLES RICHET.

We trust that these visits will in no small degree contribute to bring about the result which Dr. Richet so earnestly expresses.

NOTES.

THE Prince of Wales presided at a meeting held at Marlborough House on Tuesday in furtherance of the objects of the recently-formed National Association for the Prevention of Consumption. Sir William Broadbent explained the nature and means of prevention of tuberculous disease, and stated that the objects of the Association were (1) to educate the public as to the means of preventing the spread of consumption from those already suffering from the disease; (2) to extinguish tuberculosis in cattle; (3) to promote the erection of sanatoria for the open-air treatment of tuberculous disease. Lord Salisbury moved the following resolution approving of these objects:—"This meeting desires to express its approval of the effort which is being made by 'The National Association for the Prevention of Consumption and other Forms of Tuberculosis' to check the spread of the diseases due to tubercle, and to promote the recovery of those suffering from consumption and tuberculous disease generally. It also commends the method adopted by the Association of instructing public opinion and stimulating public interest rather than the advocacy of measures of compulsion." The resolution was seconded by Sir Samuel Wilks, the President of the Royal College of Physicians, and carried unanimously. Sir William Broadbent announced that the London partners of Messrs. Werner and Beit have undertaken to erect and equip a sanatorium for tuberculous patients at an estimated expense of 20,000*l.*, the construction and management of which will be under the guidance of the Association. The organising committee have every reason to congratulate themselves on the interest which has been excited in all parts of the country. Branches are being formed in York, Norwich, Ipswich, Huddersfield, and other towns, and at York a considerable sum of money has already been raised for the erection of a sanatorium.

THE Paris correspondent of the *Times* announces that at the annual sitting of the Academy of Sciences on Monday the Lalande prize was awarded to Dr. S. C. Chandler, the Damoiseau prize to Mr. George Williams Hill, and the Houllevique prize to Mr. Branly.

THE death is announced of Prof. H. W. Vogel, the distinguished professor of photography, photo-chemistry, and

spectroscopy at the Berlin Technical High School. Prof. Vogel was born in the year 1834, and he devoted his working life and energies to the advancement of photography.

Prof. Behring, together with Dr. Ruppel, is reported by the Berlin correspondent of the *British Medical Journal* to have applied for a German patent for a tuberculosis serum. His claim is: "A method for producing a highly poisonous and immunifying substance from tubercle bacilli, or from cultures of tubercle bacilli."

Mr. Borchgrevink, and the members of the Antarctic expedition under his charge, sailed from Hobart on Monday.

We learn from the *Lancet* that Luigi Galvani, the great anatomist of the Bolognese school, and better known for his discovery of animal electricity, received on Sunday, December 4, at Bologna, the honour of a centenary celebration—that of his death, which took place on December 4, 1798. The occasion evoked the presence of the leaders of the local medical school, and its orator was Signor Erminio Vitta, representing the Committee of Italian telegraphists now organising a similar commemoration of Alessandro Volta. The proceedings were highly successful.

On Monday evening Prof. Ramsay delivered a lecture, by special invitation, to the members of the Berlin Chemical Society in the Chemisches Institut, on "The New Gases and their Relations to the Periodic Law." Prof. Liebermann presided, and in the crowded audience were Prof. Virchow, Prof. Liebreich, Prof. von Bezold, Prof. Warburg, Prof. Fischer, and many other eminent men of science. The German Emperor and Empress visited the Chemisches Institut on Tuesday afternoon, in order personally to listen to a private exposition by Prof. Ramsay of his discoveries and methods.

It has already been announced that the Geological Society has decided to undertake the publication of the manuscript in its possession of a portion of the third volume of Hutton's "Theory of the Earth," and to accept the generous offer of Sir Archibald Geikie to edit and prepare it for the press. The third volume will be printed in the style of the first and second volumes of the same work, and will contain about 300 pages. The manuscript is now ready to go to the printers, and, as only a limited number will be issued, the Secretary of the Society would be glad to receive the names of intending purchasers.

The Rome correspondent of the *Daily Mail* reports as follows:—Some very important discoveries have recently been made in the Vatican library. While examining some State documents of the sixteenth century, the Abbé Cozza Luzzi, assistant librarian, had the good fortune to find the original manuscript treatise by Galileo Galilei on the tides. The manuscript, which was hitherto only known as N 8193, is all in Galileo's own handwriting, and ends with the words:—"Written in Rome in the Medici Gardens, on January 8, 1616." The great astronomer had dedicated the book to Cardinal Orsino, his admirer, and Mæcenas. Leo XIII. has taken the greatest interest in the discovery, and has ordered the manuscript to be published in an elegant edition at the expense of the Vatican. The discovery of this treatise, the original of which was considered lost, is all the more important as it differs considerably from the text hitherto accepted as Galileo's, and now in course of publication, together with Galileo's complete works, by the Accademia della Crusca.

Science publishes some particulars in regard to the forthcoming meeting of the American Society of Naturalists, and of the Societies holding their meetings in New York City in conjunction with it. The first meeting of the Society of Naturalists will be in the American Museum of Natural History on December 28. After a welcome by the President of the Museum, Mr. Morris K. Jesup, Prof. Henry F. Osborn will give a lecture on "Collections of Fossil Mammals and their Care." The chief meeting of the Naturalists will be held on the afternoon of December 29 at Schermerhorn Hall, Columbia University. After the Societies have been welcomed by President Low, a series of short papers will be read on "Advances in Methods of Teaching," as follows:—Zoology, Prof. E. G. Conklin, University of Pennsylvania; anatomy, Prof. George S. Huntington, Columbia University; physiology, Prof. W. T. Porter, Harvard Medical School; psychology, Prof. Hugo Münsterberg, Harvard University; anthropology, Dr. Franz Boas, Columbia University; botany, Prof. W. F. Ganong, Smith College.

At the end of last year the Council of the German Chemical Society appointed a Commission, consisting of Profs. Landolt, Ostwald and Seubert, to draw up a table of atomic weights for use in calculations incident to the practice of analytical chemistry. The report of the Commission is to be found in the last number of the *Berichte*. It is decided to take oxygen as 16·000, and to select atomic weights for other elements in direct or indirect comparison with this value. It is noteworthy that Prof. Seubert, who has hitherto stood out for hydrogen (1·000) as the proper basis for atomic weights, now concedes that for practical purposes oxygen as 16·000 is the more suitable standard. Hydrogen thus becomes 1·01. In the table as printed the atomic weights are not given beyond the last trustworthy figure, and in no case beyond the second decimal place. Nickel is given at 58·7, cobalt as 59; but these numbers are marked as open to some doubt. It is proposed to print the table annually in the *Berichte*, with any revision that may be found necessary. The wish is expressed by the Commission that there should be some international understanding on the subject of the atomic weights used in analytical chemistry; and it is remarked that the achievement of this would not be difficult, since the German table is practically the same as that issued in America by Prof. F. W. Clarke on behalf of the Atomic Weight Commission of the United States. The Council of the Society have requested the Commission to open international negotiations.

The two following items of news give support to the case for the adoption of the metric system in this country:—The Board of Trade have received information that a large amount of ironwork for bridges in Norway has been ordered from Antwerp. The contractors state that they would gladly have placed the order in England, but have lately gone over to order all their iron from the continent, because they cannot get English makers to supply the work according to the metric system, and it is too complicated for them to work it all out into English measurement, feet and inches.—At a recent meeting of the Bristol Chamber of Commerce it was unanimously resolved: "That the Council of this Chamber, in view of the repeated warnings of H.M. Consuls, and deeply sensible itself of the injury done to British trade by the delay in the adoption of the metric system of weights and measures by this country, strongly urges the Government and all public bodies to aid in making the system familiar to the public, by making use of it in their various contracts, returns, and reports."

Upon the subject of mosquitoes and malaria, the *British Medical Journal* publishes the following note:—We learn on trustworthy authority that the Italian investigators have once again succeeded in conveying to man malarial infection by means of mosquito bites. The parasite in this instance was the benign tertian; the mosquito employed was the same as that which has already proved an efficient transmitter of the malignant tertian

parasite—namely, *Anopheles claviger*. In this second successful experiment the mosquitoes were brought from a distance from a notoriously malarial spot, and liberated on the subject of the experiment in Rome. The investigators referred to have not yet discovered Ross's "germinal rods" in mosquitoes purposely fed on crescent-containing blood. We hear, however, that they have found these rods in mosquitoes brought from a distance from houses in which there had been malarial fever cases.

Mr. W. Garstang's paper on the variation, races, and migrations of the mackerel (*Scomber scomber*), published in the latest number of the *Journal* of the Marine Biological Association, is a valuable contribution to a subject of economic as well as of scientific importance. The investigation was undertaken at the invitation of H.M. Treasury, and its chief object was to discover the relation to one another of the spring and autumn schools of mackerel which regularly visit the Irish coasts. In the spring a multitude of large fish approach the south and west coasts of Ireland to breed. In the autumn, schools of immature, but usually well-grown, mackerel come around the island. These differences are explained by the facts collected by Mr. Garstang; for it appears that the Irish race of mackerel may be subdivided into two distinct stocks.

The paramount conclusion of the inquiry of Mr. Garstang into the life-history of the mackerel is thus expressed: "The mackerel which frequent British waters are not exactly alike in all localities, but possess certain average peculiarities which distinguish one local race from another. These peculiarities are greatest between the races of localities which are geographically remote, and least between those which occupy areas that are geographically contiguous. Between the mackerel of the North Sea and English Channel there are no differences at all; but the Irish race is distinctly divisible into two stocks, one of which is restricted to the west coast, the other to the south. A considerable amount of mixture takes place between the southern Irish stock and the fish which frequent the mouth of the English Channel. The western Irish stock represents more closely than any other race the primitive type of mackerel, from which all, whether British or American, have been derived." It is pointed out that the establishment of geographical or local races of the mackerel involves the rejection of the theory of long migrations.

An abstract of a study of the more stable differences of a physical nature which exist between white and negro children of the same sexes and the same ages, is given by Dr. A. Hrdlicka in the *American Anthropologist* (November). It appears that, in a general way, white children present more diversity, negro children more uniformity, in all their normal physical characters. This becomes gradually more marked as age increases. As to physical abnormalities, those of congenital origin are much less frequent in the negro child than in the white one. With acquired abnormalities, principally the result of rachitic conditions, the case is almost the reverse, those characters being less frequent in the white children.

A recent number of the *Arbeiten aus dem Kaiserlichen gesundheitsamt* contains a series of reports drawn up by medical officers resident in different parts of German East Africa. These reports are furnished in response to a circular issued by the Colonial Medical Department, containing a list of various subjects upon which it was desired to collect information. Amongst these we find vaccination, the surgical treatment of various wounds, &c., the treatment of mental diseases; whilst special attention is directed to the collection and identification, where possible, of herbs and roots employed for medicinal purposes by the natives. As a result of this circular an immense amount of most valuable and instructive information has been collected, which not only should prove of use, but is also of great interest from an historical point of view, throwing as it does considerable light on the social conditions of these natives. Some curious medical superstitions are recorded, such as the treatment of stings from scorpions by burning the sting of the insect and placing its ashes on the wound; whilst, in the absence of this remedy, salt and snuff are to be rubbed in! The mentally afflicted suffer most from the effect of superstition, however, and have to submit to what can only be described as the most cruel torture to procure the ejection of the evil spirit with which the patient is believed to be possessed. The perpetuation of the race does not seem to be regarded as of much importance, and in the case of one tribe when twins are born, one is always destroyed, usually the last born, except where both sexes are represented, under which circumstance the female is invariably sacrificed. Nothing but praise can be accorded to the enterprising spirit of the German Colonial Department, which is not alone ambitious to extend its dominions, but is equally concerned in obtaining all the information it can about the possessions which it has already acquired.

Among the subjects of papers read at the recent conference of the Society for the Protection of Birds, was the decrease in the numbers of swallows and martins coming to this country, by Mr. J. H. Allchin. One of the causes of this decrease is that swallows are netted by the thousand as they came to the shores of Italy in their northward migration, and are eaten as food; they are also caught in great numbers with artificial flies and fish-hooks; all this being contrary to the Italian law and to treaty with the European Powers, which binds Italy not to permit the netting of birds on her shores. As regards destruction of swallows on the southern coast of France, records in official publications testify to the massacre of millions, while on their passage, by means of the net, the fish-hook, and the electric wire. The chief disturbing element in England is the common house sparrow, which persecutes the house martin, ejecting it from its nest, and destroying eggs and young. Mr. Allchin proposed that the Society should present a strong protest to the Governments of Italy and France against the destruction of birds in the course of their annual migrations, and should also petition the Board of Agriculture to send a protest to the aforesaid Governments, on the ground that the destruction of the Hirundinidae and other insectivorous birds was diminishing their numbers to such an extent as to lead to a serious increase of insects injurious to our crops. He further suggested that means should be taken to destroy the eggs (but not the nests) of house sparrows, and that County Councils be petitioned to place all swallows and martins and their eggs on the protected list, and to extend the close season to the full extent of the birds' stay in this country.

Dr. Tollenaar, writing from Batavia with reference to the alleged momentary increase of temperature in one end of a bar of metal suddenly cooled at the opposite end, calls attention to the fact that the matter was investigated sixty years ago by Schröder in a paper entitled "Kaun die plötzliche Abkühlung eines Theiles einer erwärmten metallische Masse eine plötzliche Temperatursteigung eines anderen Theiles zur Folge haben?" (*Pogg. Ann.*, 46, p. 135.) In our correspondence columns will be found a letter (p. 174), in which it is stated that there is no increase of temperature in the bar when one end is cooled.

Dr. G. Ercolini contributes to the *Atti dei Lincei* (vii. 8) a note on the variations produced in the dielectric constant of glass by mechanical traction. The experiments, which agree with those of Quincke, serve to verify Lipmann's theory that the dielectric constant of glass increases with traction. The greater the tension the more closely is the increase in the constant proportional to it; at first it falls short of proportionality.

UNDER the somewhat ambitious and comprehensive title, "On kathodic rays, on Rontgen rays, and on the size and density of atoms," Signor G. Guglielmo discusses in the *Atti dei Lincei*, vii. 8, that much debatable point, the nature of Röntgen rays. The author favours the hypothesis that these rays are due to non-periodic disturbances of the ether; and seeing that the impact of kathodic rays produces in bodies a regular vibration which is fluorescence, Röntgen rays may be due to the ether entrained by the particles of the kathodic rays, and set free when these particles are brought to rest.

In the *Journal* of the Royal Statistical Society (lxi. iii.) Prof. F. Y. Edgeworth is endeavouring to show that the higher theory of probabilities is not restricted to organic nature; but the law of error is fulfilled in social life also, whenever a great number of independent causes act. Remarking that the multifarious motives which sway voters at a contested election may be expected to produce results dispersed about an average according to that normal law, Prof. Edgeworth has obtained tables of the ratio of Unionists to Gladstonians, and Unionists combined in each English constituency for the three last general elections. The grouping of these ratios shows a certain approximation to the normal form. Prof. Edgeworth also discusses the reasons for selecting the above-named ratio as the attribute to be tabulated, and shows that the values of this ratio lie more symmetrically between the mean and the extremes than those of other ratios which might be suggested.

THE report on the Administration of the Meteorological Department of the Government of India in 1897–8 shows that the observatories, 174 in number, remain practically the same as in the previous year. In order to give early information of the advent and progress of the south-west monsoon, a daily telegram was received from the Seychelles Islands from May to July. Actinometric observations have been continued as in the eight previous years, and have been sent to the Solar Physics' Committee in London. The day of the total solar eclipse (January 22 last) was remarkably fine nearly all over India, and 158 observers took part in the observations. These have been tabulated and reduced, and it is proposed to publish them in detail during the ensuing year. A large number of reports of earthquake shocks have been received during past years, and copies have been sent to the Geological Survey Department; in future a brief statement of the earthquakes of each month will be published in the *Monthly Reviews*. The results of the cloud observations taken at various stations, in accordance with the scheme proposed by the International Meteorological Committee, are said to be very interesting and encouraging, and will probably throw much light on the meteorology and more massive air currents in India. The extraction of observations made in ships' logs has been continued at several ports; these are used chiefly in the preparation of daily weather charts of the Indian monsoon area. The collection of accurate information relating to the snowfall in the Himalayan and Afghan mountain areas has been continued, and enabled its probable effect in modifying the distribution of the south-west monsoon rainfall to be determined. The work of issuing storm warnings to the various ports appears to have been carried out very satisfactorily; ample notice was given of all the more important storms which visited the Indian coasts during the year in question. The selection of weather types, to aid in the issue of daily forecasts, has been under consideration, and the preparation of an atlas and handbook, with that object in view, will probably be taken up in due course, as it is considered that there are now sufficient materials in the possession of the Department for the adequate treatment of the subject.

PROF. R. H. THURSTON calls attention in *Science* to some points of scientific interest in the report of the Chief of the Bureau of Steam Engineering upon the engineering work of the navy in the war with Spain. Some work was performed with marvellous despatch. Thus, the old and worn-out "shell-boilers" of the monitors *Manhattan*, *Mahopac* and *Canonicus*, at League Island, were replaced by new constructions in thirty days. The new water-tube boilers were passed in parts through the hatches, and the old boilers were cut in pieces below and passed up in small sections. Water-tube boilers are unqualifiedly approved for naval purposes, and experience with those of the *Marietta*, while accompanying the *Oregon* on the long 14,000-mile voyage around Cape Horn, proves that such boilers are trustworthy when properly made and handled. The steam turbine is referred to, but with the statement that it is not yet certain that it will find permanent place in the naval service. The use of oil-fuels is pronounced promising in some naval work where costs of fuel are not of prime importance. Success is met with in the use of an oil of specific gravity, 0·85 to 0·87, a flash-point of 315° F., and a burning point of 350° F.

THE new volume of "Who's Who" (A. and C. Black) contains several additional features, and more than fifteen hundred new biographies, some of which refer to men of distinction in the scientific world.

A BULKY volume of "Anales de la Oficina Meteorológica Argentina" has just been received from the Director, Señor G. G. Davis. The volume is full of statistics referring to the climates of Asuncion in Paraguay, and Rosario in the Province of Santa Fé.

A NEW part of Prof. G. O. Sars' monograph on the Crustacea of Norway has just been published by the Bergen Museum. The family Oniscidae is concluded, and members of the families Bopyridae and Dajidae are described.

IN a pamphlet entitled "A Record of Study of Aboriginal American Languages," Dr. D. G. Brinton surveys his writings in this branch of linguistics, extending over a period of forty years. The papers are arranged geographically, and sufficient reference to their contents is given to indicate their aims and conclusions.

THE November (supplementary) number of the *Oesterreichische Monatsschrift für den Orient* includes an important report from Shanghai, dealing with sericiculture in China, to which we particularly call the attention of persons commercially interested in the silk trade.

THE last number received of the *Kew Bulletin of Miscellaneous Information* (designated Appendix I, 1899), is entirely occupied by the annual list of seeds of hardy herbaceous plants and of trees and shrubs, which the Department offers in exchange with Colonial, Indian, and foreign botanic gardens, as well as with regular correspondents of Kew.

THE United States National Museum has just published a large paper of nearly two hundred pages, with twenty-two plates, by the indefatigable entomologists, Drs. John B. Smith and Harrison G. Dyar, including a revision of the species of *Acronycta* (Ochsenheimer) and of certain allied genera. With this paper is issued a set of seven coloured plates of moths and larvæ belonging to the same group, which were prepared to illustrate an unfinished paper intended to be issued by the Department of Agriculture.

PART I. of the *Proceedings* of the South London Entomological and Natural History Society for 1898 is chiefly devoted to *Lepidoptera*. The most important paper is one by Mr. J. W. Tutt, on the British *Lasiocampidae*, containing a hypothetical phylogenetic tree of the genera, and another exhibiting the phylogeny of super-families of the Sphingo-Micropterygid

stirps. There are also notes by Mr. R. South, on British *Lepidoptera* occurring in Japan; and by Mr. A. H. Jones, on some South European *Lepidoptera*, with remarks on the genera *Thais* and *Euchloe*. The only paper relating to a different order is by Mr. E. Saunders, on collecting British *Hemiptera*.

THE Royal Society for the Prevention of Cruelty to Animals has sent us the twenty-ninth annual volume of "The Animal World," and a new volume of the "Band of Mercy." Both volumes are profusely illustrated with pictures of animals, and they will assist the educational work of the Society. Children interested in animals or natural history—and what children are not?—would regard either of the volumes as an acceptable present for Christmas or the New Year.

THE twenty-first volume of *Knowledge*, containing the monthly parts published during the current year, has been received. The articles in the volume deal with many scientific subjects, but the most prominent features are astronomy and natural history. The chief contributors are Mr. R. Lydekker, who writes on various zoological matters; Prof. Grenville Cole, who deals with a number of geological structures and problems; Mr. A. Vaughan Jennings, who contributes a series of botanical studies; and Mr. E. W. Maunder, who writes on interesting astronomical objects and events. Numerous illustrations, many of them full-page plates, and including reproductions of several of Dr. Roberts's marvellous photographs, adorn the pages of the volume.

MR. WILLIAM MARRIOTT informs us that on January 2, 1899, the offices of the Royal Meteorological Society will be removed to Princes Mansions, 70 Victoria Street, Westminster, S.W., to which address all communications, on and after that date, should be forwarded.

THE Tidal Survey branch of the Department of Marine and Fisheries of the Dominion of Canada has issued a collection of tide-tables for Halifax, Quebec, and St. John, for the year 1899, with tidal differences for the Atlantic coast of Nova Scotia, and for the St. Lawrence River, from Three Rivers to Gaspe.

PSYCHOLOGISTS and students of the philosophy of science will be interested in the announcement that, under the title of "Truth and Error, or the Science of Intellection," Messrs. Kegan Paul, Trench, Trübner, and Co., Ltd., will shortly publish a new book by Mr. J. W. Powell, the Director of the United States Bureau of American Ethnology, and sometime Director of the United States Geological Survey.

THE Tuesday evening penny science lectures will be resumed at the Royal Victoria Hall, Waterloo Bridge Road, on January 3, when the Rev. R. H. Whitcombe will discourse on "Science Jottings in Switzerland." On January 10, Mr. R. A. Gregory will lecture on "Astronomy before Telescopes"; and on January 17, Prof. Farmer will lecture on "Plants as Engineers." On January 24, Mr. C. W. Andrews will give an account of his work on "Christmas Island"; and on January 31, Prof. Frank Clowes will lecture on "Old Father Thames."

A NUMBER of forthcoming works on scientific subjects appear in the *Book Circular* (No. 69, Scientific Series), just issued by Messrs. Williams and Norgate. Among the volumes announced we notice the following:—The second volume of Dr. F. Dannemann's "Grundriss einer Geschichte der Naturwissenschaften," entitled "Geschichte der Naturwissenschaften aller Völker und Zeiten."—Prof. Ernest Haeckel's lecture to the Fourth International Zoological Congress at Cambridge will be issued, with notes and tables, under the title "Unsere gegenwärtige Kenntniss vom Ursprung des Menschen."—Another work by Prof. Haeckel, which is announced for publication in January, is "Kunstformen der Natur."—A work by Prof. O. Bütschli, Professor of Zoology at Heidelberg, being a continuation of the same author's "Untersuchungen über microskopische Schäume," of which an English translation has been issued.—The second part of the second volume of Dr. Paul Knuth's "Handbuch der Blüten biologie," containing Lobeliaceæ to Coniferæ.—M. Riban, of the University of Paris, has prepared a "Traité d'analyse chimique quantitative par l'Electrolyse."—"La photographie animée," by E. Trutat, Director of the Natural History Museum of Toulouse.—A work by Prof. Lebon, of the Lycée Charlemagne, Paris, entitled "L'Histoire abrégée de l'Astronomie."—A volume by M. E. Bouty, Professeur de la Faculté des Sciences, on "Electricité à ondes Herziennes. Rayons X."

THE additions to the Zoological Society's Gardens during the past week include two Red-bellied Squirrels (*Sciurus variegatus*) from Trinidad, presented by Master Lawrence; a Palm Squirrel (*Sciurus palmarum*) from India, presented by Dr. G. Lindsay Johnson; a Pluto Monkey (*Cercopithecus leucampyx*, ♂) from Congoland, deposited; a Nutcracker (*Nucifraga caryocatactes*), a Common Sheldrake (*Tadorna cornuta*) European, purchased.

OUR ASTRONOMICAL COLUMN.

A TOTAL ECLIPSE OF THE MOON.—On Tuesday next (December 27) the moon will pass entirely into the shadow of the earth, and be totally eclipsed. The following are some of the particulars which may be useful to those who wish to observe this phenomenon, but fuller information, together with a list of stars to be occulted, will be found in the *Nautical Almanac* and the *Companion to the Observatory*.

	h. m.
First contact with the penumbra, Dec. 27,	8 26·5 G.M.T.
,, ,, shadow ...	9 39·4
Beginning of total phase ...	10 49·0
Middle of the eclipse	11 33·7
End of total phase	12 18·4
Last contact with the shadow ...	13 28·0
,, ,, penumbra	14 40·9

The moon meets the shadow at a point on her limb which is 112° from her north point towards the eastern side, and passes out at a point 95° towards the west.

The magnitude of the eclipse is represented as 1·383, the unit representing the case when conditions are such that the moon is only just able to be totally immersed for an instant.

COMET CHASE.—This comet, which is gradually brightening, is situated in the constellation of Leo Minor, and lies slightly to the north of the 6th magnitude star 50 in Leo Minor. The following is the ephemeris to the end of the present month.

1898.	R.A. (app.) h. m. s.	Decl (app.) ° ′	Br.
Dec. 22 ...	10 55 11 ..	+26 59·8 ...	1·39
24 ...	56 44 ...	27 19·0 ...	,,
26 ...	58 11 ..	27 38·8 ...	,,
28 ..	10 59 31 ...	27 59·0 ...	,,
30 ...	11 0 43	+28 19·7 ...	1·39

COMETS *i* 1898 AND 1881 IV.—Writing in the *Astronomical Journal* (Nos. 448–450), Dr. Perrine, of the Lick Observatory, points out a distinct relationship between the comet *i* 1898 and 1881 IV. The similarity of the orbits is strikingly seen from the following comparison of the orbits:—

Comet.	ω	Ω	*i*	*q*
i 1898 ...	... 122 8 ...	97 17 ...	140 14 ...	0·6335
1881 IV....	.. 123 22 ...	96 10 ...	140 19 ...	0·7564

Dr. Perrine states that although it is not possible for Brooks's comet to be a return of Schaeberle's, yet the resemblance is so close that a strong family connection is indicated. If we may be permitted to make a suggestion, might not there be two comets pursuing the same path? Just as comets are thinned out by their component parts lagging behind and following, so

to speak, in their wake, may not the first comet have undergone considerable perturbations and internal action, causing the original assembly of particles to separate into two or, perhaps, more portions? We should thus have two comets pursuing the same path, but passing perihelion at different times.

EPHEMERIS OF PLANET 1898 DQ.—We give below an ephemeris for Witt's planet for the remainder of this month. The planet is of the 12th magnitude, and will be found in the constellation of Aquarius, a little to the north of the stars η and ζ Aquarii.

1898	R.A. (app.) h. m. s.	Dec. (App.) ° '
Dec. 21	22 26 11	+1 31·8
23	30 35	1 54·2
25	35 2	2 17·0

29	44 5	3 4·0
31	22 48 40	+3 28·2

THE COMPANION TO THE OBSERVATORY FOR 1899. This handy little *vade-mecum*, which contains in a condensed form the more useful data that are of more general interest in observational astronomy, has just been issued. As the introduction states, "the present 'Companion' closely resembles that of last year," and a brief perusal of its contents does not lead us to state otherwise. Mr. Denning, as usual, is responsible for the meteor notes, and Mr. Maw has supplied numerous observations of double stars. The variable-star ephemerides have been obtained from M. Loewy's "advance-proofs," and Mr. Crommelin has communicated the list of stars which will be occulted by the moon during the lunar eclipse of December 16.

THE SOLAR DISC DURING 1897.—The solar observatories at Dehra Dun, Mauritius, and Greenwich, give us between them pictures of the disc of the sun 364 days out of the 365 in the year. We have thus practically a daily record of the spots that appear on the solar disc that is absolutely unique in astronomical photography. As we are approaching, as far as we know, a period of minimum sunspots, which, in other words, means a more quiescent state of the solar atmosphere, spots are getting less numerous, and their latitudes are becoming lower. A general summary of an examination of such photographs, as mentioned above, for the year 1897 (*Monthly Notices.*, *R.A.S.*, vol. lix. No. 1), shows that there has been a slight decrease in the daily spotted area as compared with the preceding year, the rapidity of the decline which set in after 1893 having now received a check; the decrease in faculæ has been quite considerable. The most noticeable feature has been the reduction of the mean distance of the spots from the equator. For the four preceding years the distance was 14°, but for 1897 it was not quite 8°. In both hemispheres the decline in latitude has been irregular. In the northern hemisphere the decline was very great for the first six months of the year, and was accompanied with a great decrease in spots. A secondary revival and subsequent decline and revival terminated during the year. A similar but less pronounced movement occurred in the southern hemisphere. The observations of the sun during the current year have shown that the spotted area has begun somewhat to increase again; but whether this is an indication that the minimum is now passed, or that only a temporary revival is taking place, cannot be definitely stated.

THE MELBOURNE OBSERVATORY.—The thirty-second report of the Board of Visitors to the observatory, together with the report of the Government astronomer, Mr. P. Baracchi, for the period included between July 1, 1897, and June 30 of the present year, show that the observatory is in good working order. With regard to the position of Mr. Baracchi, the Board says: "We regret to find that the Acting Astronomer still occupies the anomalous position he has occupied since he has had charge of the Observatory: his salary being that which he enjoyed prior to the retirement of Mr Ellery, and we venture to hope that the Government will soon be able to appoint Mr. Baracchi to the full position of Government Astronomer, with the emolument fixed thereto under the Public Service Act." Mr. Baracchi's report shows that the observatory has been very busy during the past year. The appointment of a new assistant has led to a slight change in the distribution of the work, which has proved advantageous. The meridian work and reduction has been extensive, and the usual time and meteorological service continued. Considerable progress has been made with the astrophotographic work, the catalogue plates being now complete and the chart plates numbering 278. By an arrangement with Mr. H. C. Russell, the Government Astronomer of New South Wales, Mr. Baracchi has decided to have all the work of measuring and reducing the plates of the photographic catalogue of the two zones done at the Melbourne Observatory, the two Colonies sharing the expense. The proposal that four young assistants, directed by one of the officers of the Melbourne Observatory, should be employed on this work, has already been sanctioned, and the work will be commenced as soon as the appointments have been made. The Victorian Government has placed on the estimates for the current financial year a sum of money for dealing with the observations in terrestrial magnetism at the Melbourne Observatory for the past thirty years. A discussion of such a fine series of observations should be of great value.

THE RELATION OF THE TOXIN AND ANTI-TOXIN OF SNAKE VENOM.

EARLY in the present year a paper on this subject, by Drs. C. J. Martin and Cherry, appeared in the *Proceedings* of the Royal Society (vol. lxiii. p. 420). A short summary of their experiments and conclusions was given in these columns. A supplementary paper has just been published by Dr. Martin (*Proc. Roy. Soc.*, vol. lxiv. 88), in which further experiments on this most important subject are detailed. They confirm the conclusions previously arrived at, that the antagonism between the toxins and anti-toxins is a directly chemical one, and is not, as Calmette and others state, due to an interaction solely produced by the agency of the cells of the organism into which these substances enter.

The present experiments were performed with the snake venom derived from the Australian tiger-snake *Hoplocephalus curtus*); the anti-venene employed was prepared by Dr. Calmette; and rabbits were selected as the subjects of the experiments. The results obtained are not only of practical importance in the treatment of snake-poisoning, but are of special interest, as they bear on the relations of toxins and anti-toxins in general. In snake venom and its antidote we possess substances of which the chemical nature is fairly well understood. A knowledge of their action (which must be regarded as typical of the whole class of toxins and anti-toxins) furnishes the key to the unlocking of the problem in diphtheria and other diseases, where the chemical investigation of the actual agents is a much more difficult matter, since they are diluted and obscured by the other constituents of the blood and body juices.

Dr. Martin finds that about the same quantity of anti-venene necessary to neutralise the venom *in vitro*, is capable of doing so also when the former is injected into the blood-stream, and the latter subcutaneously. Solutions of the two substances can be titrated against each other just like standard solutions with the life of a rabbit as an indicator. If anti-venene is introduced into the blood-stream, it is there ready to neutralise the toxin as it is absorbed from the subcutaneous tissues, and the amount found necessary by titration outside the body is just about adequate to neutralise the toxin as it makes its appearance in the blood. To be quite exact, a slighter proportion of anti-toxin is necessary under these circumstances, and this result is no doubt due to delayed chemical action owing to the dilution of the anti-toxin in the blood.

When, however, both venom and anti-venene are introduced into the body subcutaneously, Martin finds, as Fraser originally stated, that at least ten to twenty times the quantity of anti-venene must be used to neutralise the toxin. This apparent contradiction of the results first given is really a confirmation of the views of Martin and Cherry. In the first place, it necessitates the inference that anti toxin is comparatively slowly absorbed from the subcutaneous tissues. Calmette has stated that the exact contrary is the case, but adduces no experimental proofs of his statement. Brodie's (*Journ. of Pathol.*, 1897) work with the toxin and anti-toxin of diphtheria entirely confirms Martin's experiments with tiger-snake venom.

Our chemical knowledge of toxins and anti-toxins, together with what is known of the physiological mechanism of absorption, is quite in accordance with the view that anti-toxin is only capable of slowly penetrating the capillary wall, whereas the toxin passes through fairly rapidly. The toxins, both in the case of snake poison and diphtheria, are albumoses; they dialyse

slowly in dialysers constructed of vegetable parchment; they can be filtered through a gelatin film under pressure; but experiments show they are rapidly absorbed by the blood-vessels. In other words, though their molecules are large, they are not so large as those of the native proteids.

The walls of the capillaries are membranes possessed of permeabilities approximating those of a film of gelatin, and are relatively, although not absolutely, impermeable to proteids (Starling, *Journ. of Physiol.*, vol. xix. p. 311). If molecular size is the obstacle to proteid absorption from subcutaneous spaces, the same would apply to anti-toxins, for these are substances of great molecular size comparable to proteids.

The practical indication of this in the treatment of snake-bite is to inject the anti-venene intravenously, until the potency of the anti-venomous serum which is at the disposal of the public is greatly enhanced.

W. D. H.

REMARKABLE EFFECT OF THE INDIAN EARTHQUAKE OF JUNE 12, 1897.

A REMARKABLE example of the effect of the Indian earthquake of June 12, 1897, upon railway lines is illustrated by a brilliant photo-etching in the general report of the operations of the Survey of India during the years 1896-97, prepared under the general direction of Major-General C. Strahan, R.E., and recently distributed. The picture (Fig. 1), which represents the Manshai Bridge, Cooch Behar State Railway, after the earthquake referred to, is here reproduced in a reduced form.

This earthquake continues to be the theme of discussion by seismologists. One of the most important papers yet published is that by Dr. Agamennone in the last *Bollettino* (vol. iv., No 3) of the Italian Seismological Society, of which the following is a summary. At Rome, the early short-period vibrations were first recorded at 11.17 a.m. (G.M.T.), and these lasted until about 11.40, when the long-period pulsations commenced, reaching a maximum at about 11.47½. During the first interval there were five distinct maxima, all of which can be identified with those on the records from other observatories. After 11.47½ these records fail to show marked features in common, and the movement dies away more or less slowly according to the sensitiveness of the instrument employed. At Calcutta, the duration of the earthquake is variously estimated at from four to ten minutes, and at Shillong, which is close to the epicentre, at two minutes. In Europe, the duration of the disturbance, according to magnetograph records, was about half an hour at St. Petersburg, 1¼ hours at Wilhelmshaven, and 2¼ hours at Utrecht; and, according to those of different Italian seismometrographs, 1½ hours at Verona, 1¾ hours at Rome, 3 hours at Catania, and 3¼ hours at Padua. At Rome, the period of the earliest vibrations was half a second, but this gradually increased to 3·3 seconds after about 15 minutes. The pulsations which followed had a period of 11 and 10 seconds, in the records of pendulums 16 and 8 metres long, respectively, decreasing to about 8 seconds in both; and it is interesting to notice how closely the different instruments at other observatories agree in this respect. The measures of the maximum tilt of the ground during the passage of the pulsations are less concordant, but the mean of eight good observations in Italy is 12''·4, a value which agrees fairly well with that of 10'' obtained by means of the bifilar pendulum at Edinburgh. Unfortunately, for the calculations of the velocity, the recorded times at Calcutta differ by 2½ minutes, being 11.4½ (La Touche) and 11.7 (Oldham). Dr. Agamennone quotes nineteen European records of the time of the first disturbance, and the five best give a mean velocity of 9 or 11 km. per second, according to the time adopted for Calcutta. For the long-period pulsations, the corresponding estimates are 2·6 and 2·8 km. per second, *i.e.* about one-quarter of the above. Lastly, taking the period of the pulsations at 10 seconds, the velocity at 2·7 km. per second, and the maximum tilt of the ground at 12'', Dr. Agamennone finds the length of a complete pulsation, as it traversed Italy, to be 54 km., and the height of its crest (or amplitude) about half a metre.

FIG. 1.

BRITISH ASSOCIATION.

CONFERENCE OF THE DELEGATES OF THE CORRESPONDING SOCIETIES.

THE first meeting of the Conference was held at University College, Bristol, on Thursday, September 8, at 3 p.m. The Corresponding Societies' Committee were represented by Mr. W. Whitaker (Chairman), Dr. Garson, Mr. Hopkinson, Prof. Meldola, Mr. G. J. Symons, and Mr. T. V. Holmes (Secretary).

A short report, which was in the hands of every delegate present, contained the following paragraph:—

The Committee observe with satisfaction that the corresponding societies steadily increase in number, and that the total number of the members composing them also increases. For example, in the British Association Report of the Bath meeting in 1888 there is a list of fifty-five corresponding societies, having a total of 18,950 members. The Toronto Report of last year shows sixty-nine corresponding societies, having a total of 22,395 members. On the other hand, the average number of members in each society appears to have slightly decreased, having been between 344 and 345 in 1888, and between 324 and 325 in 1897. But this is accounted for by the collapse of the two federations—the Midland Union and the Cumberland and Westmoreland Association—and the withdrawal of the Royal Scottish Geographical Society between the two periods. For in 1888 these three associations numbered among them 4006 members, as many as would be found in eleven or twelve average societies.

The Committee, while regretting the absence of certain societies whose headquarters are not in London from the list of corresponding societies, add:—Fortunately, in most cases.

information as to the titles and authors of papers read before local societies not corresponding societies of the British Association may be obtained from the "Official Year-book of the Scientific and Learned Societies of Great Britain and Ireland" (C. Griffin and Co., London). The "Year-book" appears every spring, and contains lists of papers read in the previous year. It will be found that the "Year-book" and the British Association "Index" combined leave little to be desired by the inquirer after papers on any locality in the British Isles.

The following societies have been added to the list of the corresponding societies:—The Hull Geological Society, the South-Eastern Union of Naturalists' Societies, and the Astronomical and Physical Society of Toronto.

Mr. Whitaker opened the proceedings by introducing the subject of coast erosion. He remarked on the much greater ease and accuracy with which measurements of the amount of loss could be made now that maps on the scale of 6 inches to the mile were obtainable for all parts of the country. He instanced Sheppey as a good example of a place at which loss by coast erosion had been unusually rapid. On the first visit of the Geologists' Association there, the church and churchyard of Warden were untouched: on a later occasion the churchyard was found to have been injured, and coffins were sticking out from the edge of the cliff. That year they had found neither churchyard nor church. They had also seen, during the visit last Whitsuntide of the Geologists' Association to Aldeburgh in Suffolk, an example of another kind of marine encroachment. There they found cottages, sheds and gardens more or less injured or destroyed by the heaping-up of masses of shingle in or against them, the result of a storm in November 1897. The driving inland of blown sand also caused much injury to land on the coast in certain localities. As to the economical aspect of the question, there were certainly many places from which the removal of shingle from the shore should never be allowed. Indeed it should nowhere be allowed without careful consideration as to the probable result. And the quarrying of stone on the face of a sea-cliff should seldom, if ever, be permitted.

Mr. W. H. Wheeler thought that the movement of shingle along our shores was due to the action of the tides, not of the winds. Mr. A. T. Walmisley had always advocated the protection of the shore by groynes. Sea walls should be placed a short distance in front of the cliff to be protected. Mr. Vaughan Cornish said that the protection of one part of the shore was a bad thing for the rest of the district. He thought that no local shore protection should be allowed unless sanctioned by a Government Board. In any study of the effects of coast erosion the coast-guard, if the Admiralty gave their consent, would be able to render most valuable assistance. Mr. Wheeler thought the retention of a mass of shingle in front of a place a better protection than a sea wall. He would greatly approve of an attempt to obtain the services of the coast-guard in noting coast erosion, as at present he had found it very difficult to get trustworthy evidence. Prof. Meldola moved the following resolution:—"That the Council of the British Association be requested to bring under the notice of the Admiralty the importance of securing systematic observations upon the erosion of the sea coasts of the United Kingdom, and that the co-operation of the coast-guard might be profitably secured for this purpose." After some discussion the resolution was seconded by Mr. Gray, and carried.

Prof. Meldola read a letter from Prof. W. W. Watts, stating that the Geological Photographs Committee had formed a collection of duplicate photographs and lantern slides, consisting of about 250 prints and 100 lantern slides, which could be sent during the winter to any local scientific society wishing to make use of them.

SECOND MEETING OF THE CONFERENCE, SEPTEMBER 13.

The Corresponding Societies Committee were represented by Mr. Whitaker, Dr. Garson, Rev. J. O. Bevan, Mr. Hopkinson, Mr. Symons, and Mr. T. V. Holmes (Secretary).

The Chairman (Mr. Whitaker) announced that the resolution on coast erosion, passed at their last meeting, had been submitted to the Geological and Geographical Sections, both of which had unanimously supported the recommendations contained in it. It would now be forwarded to the Council.

Prof. Silvanus Thompson had been asked to bring before the Conference the importance of adopting one or two uniform standard sizes for the pages of scientific publications. All engaged in scientific investigation were greatly indebted to their fellow workers for reprinted papers, and all recognised the advantage given by uniformity of size in allowing these papers to be bound together. The great advantages of uniformity in size had caused the formation of a British Association Committee some four years ago, whose object was to prescribe the adoption of certain standard octavo and quarto sizes. The report of this Committee would be found in the Ipswich Report (1895), p. 77. The standard octavo size there recommended was—

Paper demy, pages measuring when uncut $5\frac{5}{8}$ inches by $8\frac{3}{4}$ inches. The width, measured from the stitching to the edge of the printed matter, to be $4\frac{5}{8}$ inches, and the height of the printed portion, including the running head-line, to be 7 inches.

The standard quarto size. Paper demy, the pages measuring when uncut $8\frac{3}{4}$ inches wide by 11 inches high. Letterpress not to exceed the measurements of $7\frac{1}{2}$ inches by 9 inches. It was also desirable that each article should begin a page, and, if practicable, the right-hand page. It can then be bound with other articles without the last page of a preceding article being bound up with it. Many other details would be found in the Report of the Committee, with illustrations.

Prof. Meldola said that a glance at the shelves at Burlington House, on which the publications of the corresponding societies were collected, showed a considerable amount of diversity in size. Some societies also did themselves injustice as regards paper and printing. Mr. Hopkinson thought that the chief offenders were societies which, from want of sufficient funds, published reprints from local newspapers.

Section A.

Mr. G. J. Symons said that Prof. Milne was making important observations on earthquake tremors in an unsatisfactory house in the Isle of Wight. It had been suggested that there were houses in Richmond Park suitable for the purpose, and that it might be well to approach the Government and try to obtain one for him. Or perhaps some rich man might lend Prof. Milne a house for a few years.

Section C.

Mr. Beeby Thompson said that a fine specimen of a Dinosaur had recently been discovered near Northampton. It would, however, be a very expensive work to uncover it carefully, and he wished either to obtain a grant from the British Association for that purpose, or to induce any rich people who might hear of the case to assist in providing funds.

The Chairman thought that the matter should be brought before the scientific societies of Northampton.

Section H.

The Chairman directed the attention of the Conference to the Ethnographical Survey, an investigation in which few local societies were co-operating.

Mr. Hartland, Secretary of the Ethnographical Survey Committee, said that it would greatly help his Committee if each of the corresponding societies would take up one or more branches of the inquiry. He had explained at previous Conferences that it was by no means necessary that all branches should be taken up everywhere. He would be happy to send to all the corresponding societies all the information they might require for the purpose of carrying on the work.

The Chairman hoped that the delegates would give some account to their respective societies of the discussions which had taken place at the Conference.

The proceedings then terminated.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PROF. RÖNTGEN has decided not to accept the call to the University of Leipzig as the successor of Prof. Wiedermann, who has retired, at the age of seventy-two.

IT is announced that the Queen has conferred a knighthood on Mr. W. C. McDonald, who provided the funds for the chemistry wing to the McGill University, Montreal, which was opened on Tuesday, and has made other generous gifts to the University.

THE appointment of the Rev. T. W. Sharpe, C.B., to the Principalship of Queen's College, London, should have a decided influence upon the work of the College. Mr. Sharpe has just retired from the post of senior chief inspector and head of the administrative division of the Education Department, so he takes with him to Queen's College a wide knowledge of the principles and practice of teaching.

A USEFUL list of the current scientific serials received in Manchester, with an indication of the various libraries in which they are to be found, has been compiled, under the direction of Dr. W. E. Hoyle, by Mr. C. W. E. Leigh, and published by the Manchester Literary and Philosophical Society. The periodicals are arranged geographically, according to their place of publication. The list will doubtless prove of great service to workers in Manchester and the neighbourhood, and thus assist in the progress of science. It is believed to be the first of the kind published in England; but it is to be hoped that similar lists will be published for the use of students of science in other great cities.

SIR PHILIP MAGNUS distributed the prizes at Sexey's Trade School, Bruton, Somerset, on December 17. Alluding to prospective legislation in the direction of secondary education, he said that the County Education authorities had done their work well, and trusted there would be no rivalry between them and School Board authorities, as it would involve a risk of setting back the educational clock for many years. He pointed out the advantage of teaching a boy the manipulation of a balance and the use of tools, and attached great importance to the study of English literature. He was glad to find the school providing satisfactory scientific education in a rural district, thus embodying ideas which he had been advocating for twenty years.

IN the course of an address to the members of the Yorkshire Naturalist Union at Scarborough, on Saturday, Prof. Michael Foster, the retiring President of the Union, urged upon his hearers the great necessity of co-operation in science. All the earlier naturalists, he said, sought to solve the problems which every form of life possessed. Nature was the naturalist's teacher, and the field his laboratory. It was useless to try to stop the tide of differentiation that seemed to be creeping over the scientific world. That must go on. Still, they must look for help to go forward, not backward. Prof. Foster criticised the method of teaching science in the schools, and condemned the examinations often held as prejudicial to the development of science. The minds of students were very often pushed on by compulsion and drawn on by rewards, and no encouragement was given to them to look at nature in the fields and receive from her lips the catholic teaching which she alone could give. Such naturalists as they hoped to rear must be reared apart from the schools.

THE following gifts to educational institutions in the United States are announced in *Science*:—The Lawrence Scientific School, Harvard University, has received 10,000 dollars from Mr. J. H. Jennings, for the establishment of a scholarship.—Mr. James Stillman, of New York, has given 50,000 dollars to Harvard College to cover the cost of land and buildings for a projected Harvard Infirmary, which will bear the name of the donor. In addition, Mr. Stillman will contribute 2500 dollars annually for four years.—The will of the late Charles P. Wilder, of Wellesley Hills, bequeaths 102,000 dollars to Mount Holyoke College, and the trustees of Wellesley College announce a gift of 50,000 dollars made by Mr. Wilder before his death. No conditions are attached to the gift.—The Catholic University of Washington has received the information that by the will of Daniel T. Leahy, of Brooklyn, it receives 10,000 dollars.—The University of Cincinnati has been presented by Mr. William A. Proctor with the library of Mr. Robert Clarke, containing 6704 volumes valued at over 50,000 dollars.—A fund of 100,000 dollars is being raised by the trustees and friends of Oberlin, the income from which is to be applied to the reduction of the term bills of needy students. About one-tenth of this amount has already been collected.

THE system of payment by results of examinations, which the Intermediate Education Board for Ireland still uses in distributing its annual income of about 80,000*l.*, is made the subject of criticism by Dr. Gerald Molloy in an article reprinted from the *Irish Ecclesiastical Review*, and suggestions are made as to a general policy of reform. The following statement of facts from the article points unmistakably to the need for the reform which must soon take place:—In a memorial addressed to the Lord Lieutenant of Ireland last June, the Council of the Royal Dublin Society called attention to the way in which the teaching of science, in the intermediate schools, has been "practically exterminated" by the operation of the present system. From this paper it appears that the total number of boys that presented themselves for the examinations of the Intermediate Education Board, in the years 1887 and 1888, and the numbers that presented themselves in the subjects of natural philosophy and chemistry were as follows:—

	Total number	Nat. Philosophy	Chemistry
1887 ...	4613 ...	2611 ...	1376
1888 ...	4551 ...	2565 ...	1357

But, after the lapse of ten years, it is found that while the total number of boys presented for examination had considerably increased, the number presented in these two subjects had dwindled down almost to insignificance. The figures are:—

	Total number	Nat. Philosophy	Chemistry
1896 ...	6503 ...	618 ...	359
1897 ...	6661 ...	596 ...	312

It would seem, therefore, that something has occurred in the working of the system, during the last ten years, which has practically killed the teaching of these two important subjects in the intermediate schools of Ireland. The teaching of natural philosophy has fallen from 56 per cent. of the total number of boys presented for examination to somewhere about 9·2 per cent., and the teaching of chemistry has fallen from 30 per cent. to 4·6 per cent.

SCIENTIFIC SERIALS.

American Journal of Science, November.—Irregular reflection, by C. C. Hutchins. A carefully prepared surface of plaster of Paris, and a deposit of magnesia upon zinc, approximate very closely to Lambert's law of diffused reflection. A plaster disc cut into fine vertical furrows shows a considerable departure from the cosine law. A sphere prepared by coating an ivory ball in the flame of burning magnesium follows Lambert's equation very closely. The reflection measured is that of the total energy, observed with a thermograph and galvanometer.—Separation of nickel and cobalt by hydrochloric acid, by F. S. Havens. Pinerua's process for separating nickel and cobalt, which is analogous to the author's method of separating aluminium and iron, will not give a complete precipitation of the nickel chloride. Nickel chloride is, however, practically insoluble in pure ether saturated with HCl gas, and can be separated from small quantities of the soluble cobalt salt in that medium.—The value of type specimens and the importance of their preservation, by O. C. Marsh. The origin of mammals, by the same author. These two papers were read before the Cambridge International Zoological Congress, in August last.—Causes of variation in the composition of igneous rocks, by T. L. Walker. The author reviews briefly the more common theories advanced to explain the phenomena of variation in the composition of igneous rocks from border to centre or from top to bottom, and calls attention to the part which gravitation seems to play in causing heterogeneity in eruptive rocks. Some homogeneous salt solutions, if allowed to remain at a constant temperature for a long time, become gradually more concentrated in the lower strata. It is very probable that similar concentration occurs in complex silicate magmas, particularly near the temperature of solidification. An eruptive magma would therefore tend to become acid above and basic below. In the upper horizons of the eruption there would be a gradual increase of acidity towards the centre, since the outer and more quickly cooling portion would have no time to become differentiated by gravitation. The lower portions would show an increased basicity towards the centre. This is all in cordance with observed facts.—The relation between structural and magneto-optic rotation, by A. W. Wright and D. A. Kreider. Experiments on the crystallisation of various substances in a magnetic field show no indisputable evidence of the influence of the field upon optically active structure. In the case of sodium chlorate, there seems to be a preponderance of optically active crystals when deposited in a magnetic field, but these are right-handed or left-handed in about equal proportions.

Wiedemann's Annalen der Physik und Chemie, No. 11.—Electric dispersion in organic acids, esters, and glass, by K. F. Löwe. Drude's rule, that anomalous electric dispersion is always

accompanied by anomalous absorption, receives a negative confirmation in the esters of the fatty acids and benzoic acid, which show neither. Other esters and alcohols show a rough approximation to Drude's formula. In the glasses, the relation between absorption and dispersion is undefined.—Limits of the solid state, by G. Tammann. Ostwald considers it possible that the transition from the liquid to the crystallised state takes place continuously along a Thomson-van-der-Waals isothermal. The author shows that this assumption implies the possibility of four volumes at the same pressure, and that the liquid isothermals may be followed up beyond the point of intersection with the crystal isothermals. This eliminates what Ostwald calls the meta-stable phase of crystallisation.—Contact electricity between metals and liquids, by A. Heydweiller. The author introduced minutely sub-divided metals into a narrow tube containing an electrolyte, and passed a current through the latter. Any contact electrification was then indicated by motion of the particles. He thus tested Coehn's rule, according to which bodies with a higher dielectric constant are positively charged by contact with bodies of a lower dielectric constant. Platinum, gold, tin, and other metals, immersed in various mixtures of water, chloroform, and acetone, show an agreement with Coehn's rule, but not when immersed in alcohol.—Use of a vacuum tube for thermal insulation, by A. Weinhold. In connection with d'Arsonval's claim of having employed the principle of Dewar's double bottle in 1887, the author mentions that he described the same apparatus as long ago as 1881, in the first edition of his "Physikalische Demonstrationen."

THE current number of the *Izvestia* of the East Siberian branch of the Russian Geographical Society contains several valuable papers.—M. Prein gives a list of 424 phanerogam plants collected in the west of the northern parts of Lake Baikal, and his list contains several species which are new for this interesting region.—A paper by S. V. Yastremski, on the ancient beliefs of the Yakutes (who belong to the Turkish stem), not only shows that their religion has a good deal in common with the religion of the Mongols, but also reveals traces of a worship of good-willing deities, which worship was practised by so-called "*white shamans*" (the *shaman* is the witch-priest). Traces of this worship, which has been intermingled in recent times with Christianity, are now found in epical poetry and popular songs only, but "white shamans" were known to exist not further than ten years ago. At the present time the "black shamans," or worshippers and conjurers of the bad-willing deities only, are retained.—M. S. Peretolchin gives an account of his ascent of the Munku-Sardyk peak in the Sayans, and describes a small glacier on its southern slope, surrounded by old moraines testifying to its former greater extension. Phanerogams were found up to an altitude of 10,230 feet.—N. A. Witaszewski gives interesting copies of inscriptions on the crags of the Olekma.—All papers are summed up in German.

IN the *Journal of Botany* for November and December, Col. H. W. Feilden continues and concludes his list of the "Flowering Plants of Novaya Zemlya," &c., 195 species in all, besides four Vascular Cryptogams.—Mr. E. S. Salmon describes and figures a moss new to the British flora, *Catharinea tenella*, lately found in Kent.—Messrs. H. and J. Groves describe and figure another very interesting addition to the British Cryptogamic flora, *Nitella hyalina*, discovered in Cornwall, one of the most beautiful of the Characeæ, distinguished from other species of the genus by the presence of secondary branchlets.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 24.—"On the Condensation Nuclei produced in Gases by the Action of Röntgen Rays, Uranium Rays, Ultra-violet Light, and other Agents." By C. T. R. Wilson.

By means of expansion experiments the degree of supersaturation necessary to cause water to condense on nuclei from various sources was determined. The nuclei produced in air or hydrogen by Röntgen rays or Uranium rays, or by the discharge of electricity from a pointed platinum wire, or by the escape of negative electricity from a zinc plate exposed to ultra-violet light, all require the same expansion (v_2/v_1 = 1·25, corresponding to a fourfold supersaturation) in order that water may condense on them. In moist air or oxygen exposed to ultra-violet light, nuclei are produced throughout the volume of the gas exposed to the rays; when the radiation is weak, these require as great a degree of supersaturation as the various nuclei above mentioned in order that water may condense on them; but with stronger radiation they appear to grow, and the expansion required to make water condense on them then depends on the intensity of the ultra-violet light, and on the time for which the gas has been exposed to the rays before expansion. With very strong ultra-violet light the growth of the nuclei continues even in unsaturated air till they become visible as a fog. Sunlight produces in air nuclei resembling those produced by weak ultra-violet light. Certain metals in contact with moist air produce nuclei always requiring great supersaturation in order that water may condense on them. This effect is most strongly exhibited by amalgamated zinc, with which comparatively dense fogs may be obtained on expansion.

It was found that the nuclei produced by X-rays or Uranium rays may readily be removed by applying an electric field, showing that the nuclei are identical with the ions to which the conducting power of the gas when exposed to the rays is due. Similar experiments with the nuclei produced by the action of ultra-violet light on moist air, and with those resulting from the presence of metals, showed that such nuclei do not move in an electric field. This is in agreement with the absence of conducting power.

Royal Microscopical Society, November 16.—Mr. E. M. Nelson, President, in the chair.—The President read a paper describing a very large and elaborate binocular microscope possessing many original features; it was designed and made some years ago by a friend. The description was illustrated by an excellent photograph of the instrument shown upon the screen.—Mr. Beck exhibited two slides of *Amphipleura pellucida*, mounted by Prof. Hamilton Smith in his high refractive medium; they were shown under $\frac{1}{12}$ achromatic oil immersion objectives of N.A. 1·0, and 1·25, the diatoms under the former showing re-solution very fairly, bur those under the latter were re-solved most satisfactorily.—Mr. Michael called attention to the slides of diatoms mounted in high refractive media, which Mr. Curties had brought for exhibition.—Dr. Hebb said there was a paper contributed by Mr. A. W. Waters, "on Bryozoa from Madeira," of which he gave a short *résumé*. Mr. Michael remarked that a systematic paper such as this would prove of considerable value to those who were studying the subject. Mr. Waters was at the present moment the best English authority on the Bryozoa, and their knowledge of these organisms had been systematised and made available largely by his contributions to the subject and by his skill as a draughtsman.

Mathematical Society, December 8.—Lieut.-Colonel Cunningham, R.E., Vice-President, in the chair.—Major Macmahon, R.A., F.R.S., communicated a discovery he had recently made in the theory of compound partitions.—Mr. J. E. Campbell read a paper on simultaneous partial differential equations.—The following papers were communicated in abstract: On hyperplane coordinates, by W. H. Young.—On a theorem allied to Laplace's, by Prof. W. H. Metzler.—Two problems of wave propagation at the surface of an elastic solid, by T. J. Bromwich. The two problems deal with the velocity of propagation of waves in hypothetical elastic solids. An attempt is made to find causes for the discrepancy between the observed velocities of earthquakes and those calculated by theory. The first case considered is that of a thin elastic shell (this case appears to have been solved by Lord Rayleigh, but it has not apparently been thought worthy of publication by him). The author finds that, with the elastic constants given by Prof. Milne as representing the nature of rocks at the surface of the earth, the deduced velocity has a value agreeing much more nearly with observed velocities than the velocity deduced from Lord Rayleigh's paper in the *Proceedings* (vol. xvii.). The second problem solves the hypothetical case of a thin skin fastened to the surface of a solid, the elastic constants of the two materials being supposed different. As might be expected the effect of the skin is not large, and the result only indicates that it is necessary to know the elastic constants at a depth comparable with a wave-length, before we can get a satisfactory comparison between theory and observation. Also by the same author, the influence of gravity on waves in an elastic solid, with especial

ference to the earth. The paper contains solutions of three problems which are concerned with the effect of gravity on the velocity of propagation of elastic waves in the earth. The first and second are based on a paper of Lord Rayleigh's (*Proceedings*, vol. xvii.). They show that when the wave-length is short enough for us to consider the earth as bounded by an infinite plane, the effect of gravity must be small. The third deals with the vibrations of an elastic sphere under its own gravity; here the modification appears to be considerable, when we consider the approximate elastic constants of the earth. This case is partly founded upon a paper by Prof. Lamb (*Proceedings*, vol. xiii.) on the vibrations of a sphere. The author finds that the effect of gravity is necessarily null when the order of the harmonic disturbance is zero or unity. For a sphere of the mass, size and gravity of the earth, but with rigidity about that of steel, he finds the gravest free period to be 55 minutes; without gravity the corresponding free period is 66 minutes. If the rigidity is about that of glass, the period is 78 minutes; without gravity, 120 minutes. The solids throughout are supposed to be incompressible in order to avoid the difficulties introduced by gravity. —Lieut.-Colonel Cunningham (Mr. Tucker, *pro tem.*, in the chair) drew attention to the three following exceptionally high numbers:—

$$N_1, N_2 = [2^{213}.(2^{209} \pm 1)^3 \mp (2^{211} \pm 1)^3] = (2^{210} \pm 1)(2^{210} \mp 1)^3$$
$$N_3 = [\{(2^{105} + 1)^4 - 2^{108}.(3.2^{104} + 1)\}^2 + \{(2^{105} + 1)^4 - 2^{212}.(2^{106} + 3)\}^2] = 2.(2^{210} + 1)^4.$$

The *complete factorisation* of the numbers $(2^{210} \pm 1)$ being known (see Lucas's memoir "Sur la Série récurrente de Fermat," Rome, 1879, pp. 9, 10), the three large numbers (N) are also *completely factorisable into their prime factors.* The two N_1, N_2 are of order 2^{840}, and therefore contain 253 figures; whilst N_3 is of order 2^{841}, and therefore contains 254 figures. The largest number hitherto *completely factorised* into its prime factors (so far as known to the author) is $(2^{210} + 1)$, which contains 64 figures.

Geological Society, December 7.—W. Whitaker, F.R.S., President, in the chair.—The geological structure of the southern Malverns and of the adjacent district to the west, by Prof. T. T. Groom. The structure of the district is explained on the supposition that the rocks represent the western margin of an old mountain-chain overfolded towards the west; the eastern portion of this range lies faulted down and buried beneath the Permian and Mesozoic of the vale of Gloucester. All the characteristics of a folded chain are present, namely, the profound folds, overfolds, thrust-planes, and transverse faults; and a typical Austönungs-zone is seen to the west.—The Permian conglomerates of the Lower Severn basin, by W. Wickham King. The rocks thus described are the calcareous conglomerates included in the Middle Permian of the Shropshire type, and exposed north of the Abberley and Lickey Hills. Three calcareous horizons occur, interstratified in sandstones or marls, and surmounted by the Permian breccia. It was the opinion of Ramsay and others that the materials of the calcareous horizons and of the Permian breccia had been brought from the Welsh border; but Buckland and Jukes, among others, claimed a southern derivation for those of the Permian breccia, from local hill-ranges to the south. The latter view accords with the fact that the pebbles composing these calcareous horizons, and also the broken fragments constituting the Permian breccias north of the Abberley and Lickey Hills, are coarser in the south-easterly direction, and gradually become finer to the north-west. The fragments embedded in the Middle Permian calcareous bands near the Lickey are chiefly of Archæan rocks; but in all the other districts described there are very few rock-fragments older than Woolhope Limestone. On the other hand, pebbles of dolomitic Wenlock and Carboniferous Limestones are abundant, while Aymestry Limestone, Old Red, Carboniferous, and Lower Permian sandstones occur in greater or less abundance; and all these rocks, except the Carboniferous Limestone, may be seen *in situ* near at hand to the south.

Entomological Society, December 7.—Mr. R. Trimen, F.R.S., President, in the chair.—Mr. McLachlan exhibited a series of specimens of the neuropterous genus *Tetracanthagyna*, de Selys, including a pair of a new species from Borneo, which was the largest known of all recent dragon-flies, though it was slightly exceeded in wing-area by the much more slender *Megaloprepus caenulatus*, a common Central-American species. —Mr. A. H. Jones showed about sixty species of Lepidoptera, taken round electric lights at Zermatt in August.—Dr. Dixey exhibited a series of Pierid butterflies from the Neotropical region to show the existence among them of seasonal forms. The President observed that the exhibit was of special interest, as affording the first recorded evidence of the existence of seasonal dimorphism in Neotropical butterflies.—Mr. G. T. Porritt exhibited an extraordinary variety of *Bombyx quercus*, bred in June last by Mr. W. Tunstall, from a larva found near Huddersfield. The specimen was a female of deep chocolate colour, with the band very faintly traced in dark olive.—Dr. Chapman, Mr. Lloyd, and Mr. Nicholson exhibited butterflies taken by them in Norway from June 20 to July 22, during the past summer at latitudes 60° 12′ and 69° 50′.—Papers were contributed by Mr. R. McLachlan, entitled "Considerations on the genus *Tetracanthagyna*"; by Mr. M. Burr, entitled "A List of Rumanian Orthoptera"; and by Mr. J. H. Leech, on "Lepidoptera Heterocera from China, Japan and Corea."

Zoological Society, December 13.—Prof. G. B. Howes, F.R.S., Vice-President, in the chair.—A communication was read from Mr. H. H. Brindley, on certain characters of the reproduced appendages in the Arthropoda, particularly in the Blattidæ. It was a continuation of a paper published in the *Proceedings* of the Society for 1897 (p. 903), and contained observations on the process of regeneration of the legs in the Blattidæ.—Mr. W. P. Pycraft read the second part of his contributions to the osteology of birds, which dealt with the Penguins (Impennes). The author found it necessary to divide this order into six genera. Of these *Eudyptula* appeared to represent the least specialised form of the whole group, and probably came nearest to the ancestral stock. The Impennes, as a whole, appeared to be most nearly related to the Tubinares. It did not seem possible to distinguish the skeleton of *Catarractes pachyrhynchus* from that of *C. chrysocome.*—One of the most important features of this paper related to the "secto-pterygoid," which the author described at some length. —Mr. W. L. H. Duckworth read a note, illustrated with lantern slides, on a specimen of a female anthropoid Ape which had been received from the Gaboon early in the present year, and as to which he was unable to decide whether it was a Gorilla or a Chimpanzee.—Mr. J. Stanley Gardiner read a report on the Turbinolid and Oculinoid Corals collected during his recent expedition to the South Pacific. Nine species were treated of in the paper, of which four were described as new. —Mr. L. A. Borradaile read the third instalment of a paper on Crustaceans from the South Pacific.—Dr. G. H. Fowler contributed the seventh of a series of papers on our knowledge of the Plankton of the Faeroe Channel. It dealt with the Station-data of depth, temperature, &c., of the hauls of H.M.S. *Research* in 1896 and 1897, with the chief Protozoa and Medusæ of the collections.

EDINBURGH.

Royal Society, December 5.—The Rev. Prof. Flint in the chair.—The Chairman gave a short opening statement, referring, amongst other things, to the Antarctic Expedition, to the survey of Christmas Island, to the new expedition to Socotra, and to Dr. Traquair's important memoir of the preceding session, and concluding with short biographical notices of recently deceased Fellows.—Prof. Kuenen, in a paper on the miscibility of liquids at different temperatures, pointed out the necessity of taking the vapour into account in the discussion of any case of equilibrium. The mixtures dealt with were chiefly mixtures of hydrocarbons and alcohols. In the case of ethane and ethyl alcohol, the solubility curve was shaped like a perverted S—the vapour and upper liquid line joining at the higher temperature, the two liquid lines joining at the lower temperature. A few degrees above the lower temperature at which the two liquids began to exist in equilibrium, it was possible, by moderate increase of pressure, to get the liquids to mix completely again. On the other hand, above the higher temperature at which phenol and water began to mix in all proportions, a large increase of pressure caused a separation of the liquids.—Prof. Ewart, in a paper on reversion in birds and mammals, discussed many instances of reversion either to a recent ancestor or to a remote ancestor. The influence of inbreeding as establishing prepotency in one or both of the parents was clearly shown, a prepotent parent or ancestor preventing reversion. Prof. Ewart illustrated his remarks by means of living specimens of pigeons and rabbits, and threw on the screen views of the zebra hybrids with which he had been experiment-

ing for some time. These hybrids showed markings much more like the markings of the Somali zebra than of their Burchell sire; they seemed to be a case of reversion to a very remote ancestor.

Paris.

Academy of Sciences, December 12.—M. Wolf in the chair.—Physical study of the elasticity acquired by muscular tissue in a state of physiological work, by M. A. Chauveau. The experiments cited were all carried out upon the flexor muscles of the fore arm of man, and were so arranged as to eliminate the disturbing influence of the weight of the limb. The elongations in the length of the muscle produced by a given increase of load are compared with the elongations which would be produced in inert substances, and the conclusion is drawn that the law obeyed by the muscle is given by $e = p(1 + r)$, where e is the increase or decrease of the force of elasticity which is maintained in a muscle put in statical contraction, p is the charge sustained, and r the muscular contraction.—Influence of metallic armatures upon the properties of mortars, by M. Considère. The use of iron or steel for the interior armature of mortars, although opposed by military engineers, on account of the results of tests made by tension only, is justified by the results of the experiments given.—Observations of the Brooks Comet (October 1898), made at the Observatory of Algiers with the 31·8 cm. equatorial, by MM. Rambaud and Sy.—Observations of the planet DQ (Witt) and the Perrine-Chofardet and Chase comets, made at the Observatory of Toulouse with the Brunner equatorial, by M. Rossard.—Observations, made at Athens, of the Leonid and Bielid swarms, by M. D. Eginitis.—On the examination of the singularities of a function defined by a Taylor's series, by M. Émile Borel.—On systems of partial differential equations reducible to ordinary differential equations, by M. Jules Beudon.—On the determination of the group of numerical equations, by M. Edmond Maillet.—On lines composed of rectilinear parts, by M. D. Gravé.—On the practical synchronising of regulators, by M. L. Lecornu.—On the ratio of the two specific heats of gases, by M. Louis Boltzmann. Remarks on a paper on the same subject by M. Leduc, with especial reference to the ratio found for the new atmospheric gases. The author arrives at the conclusions that the molecule of a perfect gas for which $k = 1\frac{2}{3}$ ought to behave in molecular concussions as a rigid sphere, a condition which is probably only possible for monatomic gases: in a gas for which $k = 1·4$, over an extended range of temperature, the molecule behaves like two spheres rigidly joined together, a case probable for diatomic gases only. At high temperatures, even perfect gases ought to show a diminution of k. For polyatomic gases this would be evident at ordinary temperatures.—On a curious phenomenon of adherence of metallic filings under the action of the electric current, by M. Thomas Tommasina.—On the arc with alternating currents, by M. A. Blondel.—On the transformation of the carbonate of orthocresol into a homologue of the phthalein of orthocresol, by M. P. Cazeneuve. The phthalein is produced by the action of soda lime upon the carbonate.—On the mixed phenyl-ethyl phosphates, by M. Albert Morel.—Chlorination of benzene in presence of aluminium chloride, by MM. A. Mouneyrat and Ch. Pouret. If $AlCl_3$ is present in the proportion of 30 gr. to 1000 gr. of benzene, the latter absorbs a rapid current of chlorine completely at 50 C. Fractional distillation of the product gave 760 gr. of pure C_6H_5Cl, together with 450 gr. of dichlorbenzenes. The latter can be obtained readily in quantity by similarly chlorinating monochlorbenzene, the para compound predominating.—Action of oxidising agents upon some nitrogen compounds, by M. Œchsner de Coninck. A study of the reaction between chromic acid and potassium bichromate and numerous nitrogen compounds, including hydroxylamine, hydrazines, ureas, and amides.—Action of the bacillus *Coli communis* and the Eberth bacillus upon nitrates, by M. L. Grimbert. The nitrogen evolved by the action of these bacilli upon a nitrated medium, is always at least double that corresponding to the nitrate taken; hence the nitrogen evolved cannot arise exclusively from the nitrates, but must come in part from the amido-compounds always present in the culture.—The assimilation of nitric nitrogen and of ammoniacal nitrogen by the higher plants, by M. Mazé. Details of experiments are given which confirm the conclusions of M. Müntz, that ammonia, as such, can be absorbed and assimilated by plants.—On the natural dissemination of wine yeasts, by M. Léon Boutroux. Remarks on a paper by M. J. A. Cordier. In opposition to the latter, the author holds that the theory of dissemination by insects is more in accord with facts than the theory of air dissemination.—The juice of fungi as a vaccine against snake poison, by M. C. Phisalix.—The endomorphic modifications of the gabbro of Pallet (Loire-Inférieure), by M. A. Lacroix.—On the part played by subterranean deposition in the constitution of the soil of a portion of the department of Orne, by M. Stanislas Meunier.

BOOKS and SERIALS RECEIVED.

Books.—The Gold-Fields of Australasia: K. Schmeisser and K. Vogelsang, translated by Prof. H. Louis (Macmillan).—The Micro-organism of Faulty Rum: V. H. and L. J. Veley (Frowde).—Twenty-seventh Annual Report of the Local Government Board: Supplement containing the Report of the Medical Officer for 1897–98 (London).—Annuaire de l'Observatoire Municipal de Paris, 1899 (Paris, Gauthier-Villars).—Les Recettes du Distillateur: E. Fierz (Paris, Gauthier-Villars).—Ostwald's Klassiker der Exakten Wissenschaften, Nr. 97 to 100 (Leipzig, Engelmann).—Congrès National d'Hygiène et de Climatologie Médicale de la Belgique et de Congo, première partie. Belgique (Bruxelles, Hayez).—Recent Advances in Astronomy: Dr. A. H. Fison (Blackie).—University College, London, Calendar for Session 1898–9 (Taylor).

Serials.—Engineering Magazine, December (222 Strand).—Bulletin de l'Académie Royale des Sciences, &c., de Belgique, 1898, Nos. 9 and 10 (Bruxelles).—Observatory, December, and Companion (Taylor).—National Geographic Magazine, November (Washington).—Notes from the Leyden Museum, April and January (Leiden).—Atlantic Monthly, December (Gay).—Journal of the Anthropological Institute, August and November (Paul).—Journal of the Marine Biological Association, November (Plymouth).—An Account of the Crustacea of Norway, Vol. 2, Parts xi., xii. (Bergen).—American Journal of Science December (New Haven).—Morphologisches Jahrbuch, 26 Band, 3 and 4 Heft (Leipzig).—Quarterly Journal of Microscopical Science, November (Churchill).—Memoirs and Proceedings of the Manchester Literary and Philosophical Society, Vol. 42, Part 5 (Manchester).

CONTENTS.

THURSDAY, DECEMBER 29, 1898.

HE GOLD COAST OF WESTERN AFRICA.

ne Years on the Gold Coast. By the Rev. Dennis Kemp, late General Superintendent Wesleyan Missions, Gold Coast District. Pp. xv + 279. (London: Macmillan and Co., Ltd., 1898.)

he Gold Coast, Past and Present. By George Macdonald, late H.M. Director of Education for the Gold Coast Colony and Protectorate, &c. Pp. ix + 352. (London: Longmans, Green, and Co., 1898.)

THE Gold Coast of West Africa and the Loango Coast of South-west Africa are regions of especial interest the ethnologist, for in these he is not, as he is in the ajority of African regions, dependent on such fragments information as he can gather from books written by avellers, who, to him, seem deliberately, malignly deter-ined to give as little of the sort of information an hnologist wants as possible; and only too frequently ve that little in a manner that arouses suspicion in the ind of a cautious student.

However on the Gold Coast and the Loango Coast the hnologist is not dependent on the traveller, having at his ommand a mass of information: concerning the first, in e works of seventeenth century writers, grandly supple-ented in this century by those of Sir A. B. Ellis, Reindorf, uchholtz and others; and concerning the second, in the orks of the Roman Catholic missioners, who for some oo years (1490–1670) held that region, and in this century hese have been supplemented by the works of Adolf astian. Bastian, be it granted, is a jungle of information, acking the brilliant lucidity of Ellis, and he has led many stray, from neither they, nor he, knowing that the fetish f the Loangoes and of the whole of the Fiot tribes is a chool of fetish differing very markedly from other chools, and particularly from that of the tribes Ellis ealt with. Nevertheless, Bastian's work is monumental nd exact.

The two books dealing with the Gold Coast that are ow before us, in addition to dealing with an interesting egion, are especially valuable in being not the works of ravellers spending busy, hurried, worried sojourns in the ountry, but of men resident there for considerable eriods, and of a class thrown by their occupations into ontact with the natives in ways which compel the cquisition of detailed knowledge concerning them.

We will take "Nine Years at the Gold Coast" first, oth on account of its exceptional charm, and of its being he longest record of experience there which has been published since Cruickshank's great book.

All who know West Africa know that the Rev. Dennis Kemp is one of the great African missionaries, the man who by the power of his personality and his skill in organisation has made the Wesleyan Mission at the Gold Coast one of the most thriving and successful missions in Africa. It is necessary to mention this, because you get no hint of the fact directly from Mr. Kemp. The writer, a person who has, more than most men, come under adverse criticism from Mr. Kemp, well remembers his stating at the end of a warm argument, that he believed in three things—the Christian religion, the British constitution, and Mrs. Kemp, and this he displays amply in his book. At the same time, however, he displays quite unconsciously those qualities which have enabled him to do so much good service—a perfectly honest, simple, manly spirit; militant, but suffused with an abiding chivalry. This latter quality, indeed, he displays almost too much, particularly when it comes to the representatives of other missions. Any one acquainted with the state of affairs between the Roman Catholics and the Wesleyans on the Gold Coast, might have reasonably expected that at least the former mission would not receive a kindly reference; but, no, the Rev. Dennis Kemp arrives there by praising the nuns.

It must not, however, be surmised that Mr. Kemp is so uniformly benign as to be uninteresting to the un-regenerate reader; far from it. He says some exceedingly harsh things about white traders and natives; but he also gives us, so frankly, many stories of native honour and kindly helpfulness, that they almost take the sting out of his general remarks on the character of the African. He says also:

"I do not remember meeting with a merchant who was altogether regardless of the welfare of the natives. I have met with many who have taken the deepest interest in their advancement."

So we may conjecture that even traders are not hopelessly bad in Mr. Kemp's eyes.

Mr. Kemp's criticism on native character is interesting, but we venture to think that on the whole it is too severe. Cowardice, theft, and lying, are certainly not its most prominent characteristics; but it must be remembered that the people of whom he is writing, the Tshi and Gâ speaking peoples, are people who have been subjected to the disintegrating effects of alien culture. To the north they have been played on by the Muhammedanised Berbers of the Western Sudan; to the south by Europeans of divers kinds. That after some 400 years of this sort of thing the Gold Coast native should be as good as he is, is a thing highly to his credit, and that he also preserves a quantity of excellent fetish is a subject of congratulation to the ethnologist.

The main interest of the book to us here is the amount of fetish information which it gives. Of course it does not give one-quarter as much as it might; for example, Mr. Kemp frequently mentions, with pleasure, the conversion of a fetish priest, and adds that these men confess their past impositions; but Mr. Kemp keeps those confessions to himself in an irritating manner. Still there is much highly interesting information given, and although "Nine Years at the Gold Coast" is naturally written from a missionary standpoint, this does not detract from its value, for never for one moment does Mr. Kemp's point of view lead him to telling half-truths; when he once mentions an incident, you have it whole with all its instructive, pathetic and amusing atmosphere. Never for one moment does he fail in his belief in the efficacy of mission work; never for one moment is he pessimistic about it, or anything else, though he will tell you things about the mission convert that a more nervous man would omit. Here, for example, is a delightful story.

"The account of a palaver between two Christians which is not given in the Annual Report, but it is furnished by the superintendent who assisted at the settlement of the matter. Vendors in the market-place are for the most part representatives of the gentler sex. It sometimes happens that two, or more, will engage in hot dispute. Their angry voices may be heard above the din of a thousand of their sex peacefully engaged in lawful trade. There was an occasion when, as at Philippi, Sisters Euodias and Syntyche were not 'of the same mind.' 'Softly, softly,' said one to the other, 'we are Christians; let us go to the minister.' To the minister they went. The elders of the church were summoned, and then for a time superfluous steam was allowed to escape in yells, shrieks, and frantic gesticulations. Care was taken that the disputants were separated by at least a table or a desk, so as to prevent the one doing bodily harm to the other. In a few moments comparative order was restored, the whole case stated, the opinions of the elders expressed, and the outside world knew nothing of what had occurred."

That this was a great improvement on the ordinary market-place row, there is no doubt; and the vision of the active elders interposing desks and tables between the ladies is very pleasing. Most cordially also do we recommend the account given by a colleague of Mr. Kemp's, of his experiences when taking over a district to all those who think missionaries lead a life of luxurious calm.

"The house had been deserted for some time. The white ants had attacked the floor, and dry rot had set in. When I put my foot on the floor, it went below; as also did three of the legs of the chair in which I attempted to sit. The roof served little purpose but for the study of astronomy. The house swarmed with mosquitoes, and the 'kotokrodu' in legions had taken up their abode in the missionary's bed-chamber. There were myriads of black ants conveying mud from my walls to make themselves a home in my room. On sweeping the floor by means of a plank placed crosswise, I removed buckets full of refuse, and in doing so disturbed swarms of beetles, many as big as miniature clock-weights. There were rats galore, and one snake. There was a vampire, which I succeeded in securing; it measured twelve inches by two. . . . Night came on, but it was made hideous by the unearthly yells of a pair of jackals. Dropping upon an old bed, which had seen no linen for a long time, I gathered the mosquito curtain around and essayed to sleep. But I had made my calculation without reckoning with the buzz of mosquitoes and the visits of rats. I had thought that the bed was for my use, but a mother of the rodent tribe and her family were there to dispute the point with me. As, however, might and right prevailed, my visitors took their revenge on my under-clothing, and left by the morning little but buttons, and, as the Irishman says, a bundle of holes stitched together."

Mr. Kemp's book also contains an interesting description of the Ashantee country and of many journeys made into the bush, and to the many towns of the Gold Coast, and it abounds with anecdotes of personal experience. All these together go to give us a vivid picture of life in that region, making the book at once interesting to those who need not go there, and highly useful to those who must.

The main interest of the remarks Mr. Kemp makes on fetish, lies in his bringing forward so prominently the influence of coincidence in supporting the belief in it. The series of stories and the accounts of charms given in the pages 100–133 bring this point out very clearly, and are well worthy of study. And although Mr. Kemp's definition of fetishism is not what one could call sympathetic, in the main it is exceedingly accurate.

"Unlike the religions of other heathen countries, fetishism is represented by very few idols. It is a most unusual thing to see a pagan adoring a block of wood or stone. No heathen temples adorn the land, no elaborate ritual accompanies the ceremonies, no sacred writings are found in which the traditional beliefs of the ancients might be expressed. The religion, which is one of the lowest forms in existence, consists mainly of superstitious beliefs—largely aided by witchcraft—which have been handed down from generation to generation by a succession of priests, who delude the credulous minds of the people by their fraudulent practices. Fetishism is essentially spirit-worship, but of so debasing and demoralising a type as to be hardly distinguishable from devil-worship. As stated in an earlier chapter, the heathens certainly acknowledge their belief in a Supreme Being, the Creator of all things, with Whom, however, it is quite impossible to hold any communication. They live in constant dread of subordinate deities, who are always prepared to visit with wrath the individual or nation at large. The residences of these beings are known as fetish."

This last statement is so correct, at any rate for West and South-west Africa, that the student of this great nature religion called fetishism should constantly bear it in mind, as it will save him from the errors that have arisen from customary use of this word.

The beautiful series of illustrations in this book also add greatly to its interest and value; and we sincerely hope before long Mr. Kemp may be induced to give us further information, particularly those confessions of the converted fetish priests.

We have not left sufficient space to do justice to Mr. MacDonald's book. It is, with the exception of having no index, a most excellent and careful arrangement of material, that in its scattered state is available only to those who have time and opportunity to work in libraries. Mr. MacDonald has devoted much time and care to placing this material at the service of people, who though not having ready access to libraries yet are in touch with the affairs to which authorities like Ellis, Bosman, and Reindorf refer. In addition to doing this, Mr. MacDonald gives an immense amount of thoroughly useful and practical local information, thereby making this book of his a thing no one dealing with the Gold Coast can dispense with. We wish he had given us more personal comment on affairs there; but the fact of his position and long residence on the Gold Coast makes us take what he chooses to quote without comment from other writers as things proved to be true by his experience. We should like to point out his statement on p. 4, where he says the Ivory Coast is "now known as French Guinea." This is not the case entirely. In 1890 the French possessions in West Africa were, for administrative purposes, divided into Senegal, the French Sudan, French Guinea with Dahomey. But the term French Guinea is customarily restricted to the Fouta Djallon region, and the region Mr. MacDonald refers to is still known as the Côte d'Ivoire. Mr. MacDonald's observations on the Kru tribes are also slightly misleading. It is a matter of regret that so many white men, with so many opportunities of studying these interesting tribes, do not do so; confining themselves to

superficial observation and stereotyped opinion. Certainly we should have hesitated to say:

"Of all the African tribes belonging to the West Coast, the Kru boy lends himself most readily to imitation of the European."

The resistance of these tribes to alien culture being exceedingly marked. Be it granted the Kru man will acquire all the European clothes he can while he is away on his term of service; the influence these things have on him is, as Dr. Wrenchen would say, "merely external," and the secret of his going ashore at "we country" on his return there, got up in the extraordinary costume he does, lies in his relations not being able to appropriate his personal property; his general property, the things he cannot wear, are their prey. The State organisation of the Kru tribes is a subject of especial interest. In all West African tribes the tendency of property to become family instead of individual is strongly marked; but, owing to the isolation the Krus have enjoyed in their own country, it is to be found in its most marked state amongst them. Mr. MacDonald also repeats the customary accusation against them of cowardice; but in this connection it should be remembered, firstly, that the Kru men met down the Coast away from their homes, as labourers and canoe-men, are of the class called by them *Kedibo*. They are the young men of the communities; they have in their own country little influence, or power, until they have amassed enough wealth to rise to the grade of the fighting-men, the *Sedibo* class, and when they do this they usually remain at home in "we country"; and the courage of the *Kediboes*, even as Mr. MacDonald, indeed, states, when it comes to surf work, is undoubted. Secondly, it must be remembered that all African fetish worshippers are apt to dislike being killed in any way far away from home; at home they do not so much object. The explanation is simple. Away in an alien land their funeral rites cannot be properly carried out, and therefore they stand the chance not only of losing their lives, but their souls into the bargain. We only mention this matter, however, in order to induce so able an observer as Mr. MacDonald to bring his attention to bear on the interesting subject of the Kru tribes, for information regarding them is of high ethnological importance. M. H. K.

A HERPETOLOGY OF EGYPT.

Zoology of Egypt: Volume First, Reptilia and Batrachia. By John Anderson, M.D., LL.D., F.R.S. Pp. lxv + 371; 59 pls. (London: Quaritch, 1898.)

WHEN, some six years ago, Dr. Anderson undertook the investigation which has resulted in the noble work now published, our knowledge of the herpetological fauna of Egypt was very meagre indeed, and could not compare with that of the neighbouring countries such as Tunisia, Algeria, and Syria. A list of the reptiles and batrachians of Egypt showed an imposing array of species, many of which now prove to be merely nominal, but these were represented in museums by a small number of specimens, few of which bore indications of exact localities. In fact, such material as then existed was quite inadequate for a study of the distribution as required by modern zoology, and the most important subject of variations and delimitation of species could not be attacked.

The author's first task was therefore the bringing together of a large number of specimens, from as many parts of the country as possible, and this was carried out by him with extraordinary energy during successive visits to Egypt in the winters 1892 to 1895, his personal investigations extending even to Suakim, beyond the limits of Egypt proper. Not only did Dr. Anderson himself and with the help of natives succeed in collecting a very large series of specimens, many of which were brought home alive and could be sketched in natural colours and attitudes, but he was also fortunate enough to enlist the co-operation of many residents and visitors interested in natural history matters; the result being the splendid collection the bulk of which has been presented to the British Museum, a second, nearly complete set having been reserved for the Museum of the Egyptian Government School of Medicine at Cairo.

The work comprises not merely an account of all the reptiles and batrachians of Egypt proper, but also includes those that are known to occur on both sides of the Nile as far south as Wadi Halfa, to which the species met with in the district of Suakim, on the littoral of the Red Sea, are added. The few species that have been accorded from the Nile Valley as far south as Khartum, Kordofan, and Sennaar, are incidentally noticed.

Egypt forms part of a zoological sub-region, extending from the western confines of the Sahara to the desert tracts of North-western India, combining features of the two regions to which it is transitional, viz. the Palæarctic and the Æthiopian, with an endemic element specially adapted to desert-life. One of its striking features is its poverty in batrachians, the valley of the Nile from Khartum to the Delta possessing only three species of the tailless order, one of which has a wide distribution in Europe and Asia, the two others being found over nearly the whole of Africa south of the Sahara. Tailed batrachians, represented in the British Museum by some undetermined Salamandrine larvæ stated to have been collected at Ramleh, near Alexandria, have escaped Dr. Anderson's diligent search in the Mediterranean littoral. The reptiles are represented, within the geographical limits adopted in this work, by one crocodile, two chelonians, forty-two lizards, three chameleons, and twenty-eight snakes, numbers not above those of previous estimates, the additions made by the author being counterbalanced by the relegation to synonymy or the degradation to varietal rank of many a form looked upon by previous herpetologists as a species.

Of the two categories of systematists suggestively if inelegantly designated as "lumpers" and "splitters," Dr. Anderson must unhesitatingly be classed among the former. Although, we think, he occasionally goes a little too far, as when he hints at the possible specific identity of *Chamaeleon calcarifer* and *Ch. calyptratus*, *Acanthodactylus savignyi* and *A. pardalis*, *Echis carinatus* and *E. coloratus*, his treatment of the difficult subject of species commends itself to the philosophical naturalist as affording a much clearer insight into the problems of distribution and variation than could be obtained with the opposite system so much in vogue at

the present day. As examples we would point especially to his masterly accounts of *Ptyodactylus hasselquistii* and *Chalcides ocellatus*, which may be recommended for study to any who should still doubt the derivation of what are called species, or who, unable to devote themselves to original investigation of this kind, and influenced by statements of ignorant or prejudiced writers, persist in looking upon species as definite units in nature. In these examples we see how forms that are so different in their extremes, in size, scaling, and coloration combined, that one would unreservedly refer them to distinct species, are connected by such insensible gradations that it is with the greatest difficulty, and only by drawing arbitrary limits, that we are able to break up the series into a number of varieties; and how these chains of varieties correspond with the direction of definite lines of geographical distribution. In order to render the degree of individual variations more readily intelligible, long lists of measurements and tabulations of details of lepidosis are appended; these tables will prove of lasting value, from the care and completeness with which they have been drawn up.

It is only to be regretted that this exhaustive treatment of variations outside the limited range of Egypt has not been carried out through the whole work, as it would have yielded highly interesting results in the case of *Latastia longicaudata*, *Eumeces schneideri*, *Mabuia quinquetaeniata*, *Naia nigricollis*, and *Bufo regularis*. In fact, a little inconsistency in the general plan—some families being characterised whilst others are not—together with the omission of anatomical details which an author so well qualified to deal with these matters might have been expected to furnish, are among the few defects we notice in this admirable work.

The coloured plates, forty in number, mostly the work of Mr. P. J. Smit, equal, if some do not even surpass, the best that have ever been published of a group of animals particularly difficult to depict in life-like attitudes. We would specially commend, as high examples of artistic skill combined with scrupulous attention to details, pls. xiv. (*Uromastix aegyptius*), xxix. (*Chamaeleon vulgaris*), and xxxviii. (*Zamenis diadema*). Numerous black plates and figures in the text, drawn by Messrs. J. Green, Smit, and Groenvold, complete the illustrations, one specimen at least of every species known from the area dealt with being represented.

The introduction, dealing with the physical features of the region, is illustrated by a series of exceedingly beautiful photographs in electrotype, as well as by a map showing all the localities whence the specimens described were obtained.

Appearing at the moment when the whole nation is rejoicing over the re-establishment of Anglo-Egyptian rule beyond the limits of Egypt proper, this first instalment of a work on a fauna too much neglected since the days of the famous French expedition, will be especially welcome. It is therefore to be regretted, in view of the increased interest which will no doubt henceforth be taken in the natural history of Egypt, that the small number of the issue—100 copies only—will render the circulation of the book more limited than it deserves.

G. A. BOULENGER.

A BOOK WITH TWO NAMES.

Quick and Easy Methods of Calculating. A Simple Explanation of the Theory and Use of the Slide-Rule Logarithms, &c. With numerous Examples worked out by Robert Gordon Blaine, M.E., Assoc.M.Inst.C.E. &c. (London: E. and F. N. Spon, Ltd. New York Spon and Chamberlain, 1898.)

THE author makes his title, "Quick and Easy Methods of Calculating"—at least, that is all that is in large print on the title-page; but the binder calls it, on the outside of the book, "The Slide-Rule." The binder is right. The author gives a very short account of some methods of shortened arithmetic, in which he points out that it is unnecessary to work out the results of an observation with very great or unlimited accuracy when the observation itself is subject to well-known possible errors. He might have traced the connection between the desired accuracy of the arithmetic and the probable accuracy of the observation as dependant on its form, but he has not. There is a simple non-algebraical and very clear explanation of logarithms; then the real object of the book, an explanation of the slide-rule, follows. As in all explanations of the slide-rule that are published, however clear and obvious they may be to the user of the slide-rule, there is, of necessity perhaps, such an amount of detail and of rule as to possibly scare any would-be user of this invaluable instrument with the fear that he could not hope to remember it all. The writer of this notice has always felt that this difficulty can only be overcome by half an hour's personal explanation, in which case a book becomes unnecessary; however, for those who cannot meet with this personal assistance, the little book before us is clear, logical and accurate. A great number of examples, mainly derived from the engineering laboratory, are given, which serve both to show the great scope of the slide-rule and as exercises in its use.

By way of criticism, the writer would point out that to find cube roots it is preferable to use the slide inverted to set 1 on C against the cube on A, and find at what part of B and D identical readings face each other. Any reading except 1 can be found twice on A, and three places on B and D can be found for the cube roots of n $10n$ and $100n$. The rule that the writer has always given in order to know where to read is as follows: If the cube has 1 (4, 7, &c.) digits the cube root will be found on D to the left of the left possible setting on A. If it has 2 (5, 8, &c.) digits the cube root will be found on D between the possible settings on A, and if 3 (6, 9, &c.) it will be found on D to the right of the right setting on A. This very simple rule has the advantage of never failing. Unfortunately the rule, as given by the author for the less convenient method with the slide not inverted, does not answer, except by chance, for the example he himself gives to illustrate it; for, according to this rule, $\sqrt[3]{638} = 8{\cdot}6 +$ (as given without the $+$ by the author) or $= 1{\cdot}855$, but this is really $= \sqrt[3]{6{\cdot}38}$.

The writer has always felt that though rules for the number of digits may be worth formulating, they are not worth using or remembering; also that the memory is needlessly taxed by any system of instruction such as is

given in the book under notice, even though the principles are perfectly explained, where every different operation has the necessary setting of the rule explained or expressed by a diagram as a different setting or operation. If once the common rule applying to all logarithmically divided scales, whether of numbers, their powers, or of trigonometrical functions, whether ascending together or some inverted, is made clear, the sixth or slide-rule sense has a chance of being developed, and then there is no occasion to remember rules any more.

The author does not mention even the existence of a P line in some rules, which make calculation with fractional indices, or indeed indices of any magnitude as quick and direct as simple proportion, nor does he refer to Lanchester's radial cursor, which enables the slide-rule to be employed for calculations on heat engines and thermodynamics generally so that any adiabatic has its coordinates numerically presented, and even entropy is simply presented.

The quick and easy methods of calculating title is belied by there being no mention of any arithmometer.

C. V. B.

TECHNICAL BACTERIOLOGY.

Manual of Bacteriological Technique and Special Bacteriology. By Thomas Bowhill, F.R.C.V.S., F.R.P.S. Pp. xii + 284. (Edinburgh: Oliver & Boyd, 1899.)

THE scope of this manual may be gathered from the following brief summary of its contents:—Introduction; classification and morphology of bacteria; methods of sterilisation. Part i. Principles of bacteriological technique. Part ii. The preparation of nutrient media, and methods of cultivating bacteria. Part iii. Special bacteriology. Part iv. Mould fungi. Part v. Yeast fungi. Part vi. Protozoa or animal parasites.

The first eighty-six pages deal with bacteriological technique, and the author is to be congratulated on having placed the subject before his readers in a clear and concise manner, and in such a way as greatly to facilitate reference. Moreover, there is much that is new, or comparatively new, in this portion of the manual: *e.g.* method for inoculating rabbits for the diagnosis of rabies; Bowhill's method of staining flagella and bacteria simultaneously with orcëin; Roth's method of examining butter for tubercle bacilli; Neisser's method for the differential diagnosis of diphtheria bacillus in cover-glass specimens; points to be observed in describing an organism; inoculation of animals (subcutaneous, intravenous, into the lymphatics, into the serous cavities, &c.), observation of animals after inoculation, and post-mortem examination of animals.

The methods of examining air, water and earth are not treated as fully as might be wished. In examining soil, Fraenkel's method only is described. Fraenkel advocates the direct mixture of the soil with the nutrient gelatin. But the number of bacteria per gramme of surface soil is over one million. Hence to obtain separate colonies it is evident that either an almost imponderable fragment of soil must be used, or else an exceedingly large amount of nutrient material. There can be little doubt that the only practical method is to dilute the soil very largely with sterile water, and to make cultivations from the resulting mixture of soil and water.

Elsner's method for separating *B. coli* and *B. typhi abdominalis* is given, but the phenol-gelatin method, which many observers find more useful, is not described in this section of the work. In Part iii., however, reference is made to the method of separating the typhoid bacillus by carbolising the water, and incubating it with an equal part of sterilised peptone-salt solution, and thereafter making Elsner potato-gelatin plate-cultures. No description appears to be given of the method of filtering large quantities of water through a sterile Pasteur filter, brushing the surface of the filter with a sterilised brush into a few cubic centimetres of sterile water, and from the filter brushing suspension of bacteria and water, making *surface* plate-cultures in phenol gelatin.

The terminology adopted as regards the number and arrangement of the flagella of bacteria, which, as the author states, is borrowed from that applied to the Protozoa, is open to some criticism, and is hardly to be recommended.

The second and most important section of this manual deals with Schizomycetes, Blastomycetes, Hyphomycetes, and Protozoa.

It might be anticipated that a veterinary surgeon of Mr. Bowhill's reputation would give an account of some of the diseases caused by micro-organisms which affect the lower animals, and which are either not described at all, or are described in an imperfect manner in the ordinary text-books of bacteriology. Nor is this hope in vain, for the author writes lucidly and with all the authority of an expert about such diseases as swine fever, swine plague, swine erysipelas, pleuro-pneumonia contagiosa bovis, broncho-pneumonia bovis, grouse disease, &c. Moreover, glanders, diphtheria and tuberculosis, as they affect man and animals, are ably dealt with.

It is to be regretted that the author has given no description of *B. enteritidis sporogenes* (Klein), especially when it is considered that the spores of this anærobic micro-organism are found in the excreta of some of the lower animals, and that it appears to be causally related to acute diarrhœa in man. As the author is well up to date in nearly all respects, we hope to find this omission remedied in a future edition. That a new edition will soon be called for need not be doubted, as there is certain to be a large demand for a work of such sterling merit as this one undoubtedly is.

In the concluding portion of the book—Part vi., Protozoa—an excellent account is given of Texas cattle fever, plasmodium malariæ, &c.

We cannot give unstinted praise to the illustrations. Some, indeed, are very good, but many of the photomicrographs are disappointing. However much we may welcome the author's orcëin method of simultaneously staining bacteria and their flagella as an aid to the differential diagnosis of bacteria, we cannot, to judge by the results, regard it as a good method where reproduction is aimed at. The author represents *B. coli communis* as multi-flagellated. The true *B. coli communis* has only one to three flagella.

While we have ventured to indulge in a few possibly adverse criticisms, we are careful to conclude with the

remark, namely, that no student, or even expert, not only in veterinary but also in medical and sanitary science, can afford to be without a copy of this excellent manual.

The type, paper, and binding, reflect great credit on the publishers. A. C. HOUSTON.

OUR BOOK SHELF.

Elementary Botany. By G. F. Atkinson, Ph.B. Professor of Botany in Cornell University. Pp. xxiii + 444. (New York: Henry Holt and Co., 1898.)

THIS is one of the best little books of its kind it has been our lot to look through for a long time. Pleasantly written, admirably printed and illustrated, it forms an excellent introduction to the study of the science of botany, and Prof. Atkinson is to be congratulated on the way which he has fulfilled the task he has set himself.

The book opens with a general account of a plant-cell and protoplasm, and the student is led through a simple course of vegetable physiology to investigate the ways in which plants live, move, and have their being. This method of beginning with physiology is novel, and there is a great deal to be said for it. It is calculated to arouse the interest which in the minds of all inquiring people, be they children or adults, always accompanies experiment. Prof. Atkinson has wisely limited his selection of experiments to those which require apparatus of only the simplest kind, but they are for the most part experiments which give an insight into the marvellous organisation and concomitant functional complexity which are characteristic of plant-life in general.

Then there follows an elementary account of the main groups of the vegetable kingdom, illustrated by well-chosen types. But the author by no means limits himself merely to these, and the connections and relationships of the different groups are clearly indicated. The chapters on Gymnosperms, which include a good account of the occurrence of antherozoids in Gingko and in the Cycads, are especially good.

The chapters on the general morphology of the flowering plant are perhaps rather advanced, and it might be questioned whether a little more attention to external morphology might not be desirable. The part of the book specially dealing with natural orders strikes us as the least attractive part of the book; but also it is far the most difficult, within narrow limits of space, to render either interesting or educationally valuable. Possibly in a future edition of the work the author may see fit to expand this part by the inclusion of more indications of the facies of, as well as of the trend of differentiation in, the different natural orders, even if the characters of biological interest have to be omitted.

The latter class of characters (biological) are, however, specially treated in the division on Ecology. In this part of the book the author has brought together, in addition to well-known examples, the fruits of his own observation in a country in which such research cannot but yield fruitful results. And the advanced, as well as the elementary, student will find much that is new and interesting in these last chapters. Of course the treatment is brief, but it is useful; the figures and many (not, however, all) of the illustrative photographs from nature are quite admirable.

From the above brief sketch it will be seen that the book is one which thoroughly deserves to be commended as calculated to attract instead of (as is too often the case) repelling the beginner. J. B. F.

Animals of To-day, their Life and Conversation. By C. J. Cornish. Pp. xii + 319. (London: Seeley and Co., Ltd., 1898.)

MR. CORNISH is such a bright and entertaining writer, and has also the art of looking at well-worn subjects from such new points of view, that the republication of this series of articles from the *Spectator* may be welcomed by the zoologist as well as by the general reader. The author, it need scarcely be said, makes no pretence to study animals from a purely scientific or systematic standpoint; and regards the various domesticated breeds as meriting fully as much attention as their wild relatives. The adaptation of animals to their surroundings, the manner in which they exist under what appear to us unfavourable conditions, their speed, their antipathies, their susceptibility to human diseases, and their mental capacities and disabilities, form, indeed, some of his favourite subjects. But he also gives dissertations on the beauty and suitability to their uses of several domesticated breeds; while his chapters on acclimatisation, game-preservation, and, above all, on the terrible devastation inflicted on big game by "skin-hunters," are of almost absorbing interest.

In the commercial aspect of the subject, Mr. Cornish shows that while myriads of South African animals have been recklessly exterminated for the sake of their skins, yet that in Australia, where the marsupials are killed off in thousands from necessity, their valuable furs are for the most part wasted. And here it may be mentioned that, in referring to the commercial quotations of South African skins, the author makes merry at the inclusion of those of the "quagga," on the ground that the animal so-named is now extinct; but he ought to have known that at the Cape this title is universally applied to Burchell's zebra.

As beasts of burden for routes like that to the Klondike, the author speaks enthusiastically of the reindeer and Bactrian camel. Of the latter animal he observes that Englishmen have no practical experience; but if he had read the records of the second Yarkand expedition, he might have somewhat modified this statement. Wider reading might, indeed, in several cases have been an advantage to the author. For instance, in the chapter on "Thirsty Animals" he is very sceptical as to the power of any mammals to exist for a length of time without access to water; suggesting that the well-known instance of the giraffes in the Kalahari may be due to the presence of undiscovered sources of water in the interior of that desert. Had he been acquainted with Mr. W. T. Blanford's observations on the existence of certain Indian mammals in waterless districts, his scepticism might have been removed. Again, in another place, he is under the impression that wild dogs (*Cyon*) are nearer to domestic dogs than are wolves and jackals.

Such slight blemishes detract, however, but little from a very entertaining and instructive volume. Had we more writers of Mr. Cornish's stamp, the popularity of zoology, great as it undoubtedly is, would probably be largely augmented; and his present work can scarcely fail to increase his reputation as a successful writer.

R. L.

Text-book of Algebra. By G. E. Fisher, M.A., Ph.D. and I. J. Schwatt, Ph.D. Part I. Pp. xiv + 684 (Philadelphia: Fisher and Schwatt, 1898.)

ON the whole this is a sound and instructive book. In the chapters on first principles the distinction between signs of operation and signs of quality has been very properly emphasised by a special notation, instead of being ignored; the treatment of systems of equations is excellent; and that of surds is much better than usual, although exception might be taken to some of the notation, and the existence of $\sqrt{2}$ as a definite number cannot be proved (as the authors seem to think) by considering the diagonal of a unit square. The book is rather unequally written, and errors sometimes occur which contrast curiously with the accuracy which generally prevails. Thus in the proof of the remainder theorem the same symbol Q is used for two entirely different things; it is assumed without proof that if r is a proper fraction r^m be-

comes infinitesimal as n increases indefinitely; and it should have been stated explicitly that i is a *definite* symbol obeying the law $i^2 = -1$, together with the usual laws of operation, and that if a is positive $\sqrt{-a}$ is understood to mean $\sqrt{a} \odot i$. If these last precautions are not taken, it cannot be proved, for instance, that $\sqrt{-a} \times \sqrt{-b} = -\sqrt{ab}$, and, in fact, the authors' treatment of this identity is defective. Then such problems as "factor $a+b$" are perfectly unmeaning, especially after chapters on surds and complex numbers; probably the answer intended is $(\sqrt{a}+i\sqrt{b})(\sqrt{a}-i\sqrt{b})$, but any number of others might be constructed, for instance $(\sqrt{a}+\sqrt{b}+\sqrt[4]{4ab})(\sqrt{a}+\sqrt{b}-\sqrt[4]{4ab})$, and so on. It ought to be unnecessary to say that all questions on factors should be put in a perfectly definite way.

It is a pity that the elementary theory of graphs has not been included; every teacher who has tried the experiment must have realised the value of plotting off the graphs of even the simplest functions such as x, x^2, $x/(1-x)$, and so on. Another remarkable fact is that not a single word is said about partial fractions: this is a serious omission, and, in fact, a whole chapter on rational functions might be added with advantage.

This volume ends with a chapter on the binomial theorem for a positive integral exponent. The examples are very numerous, and appear to be well graded: they are intended to provide teachers with alternative sets for different years. The student should on no account try to work them out *seriatim*. G. B. M.

Distribution de l'énergie par courants polyphasés. By J. Rodet. Pp. 338. (Paris: Gauthier-Villars, 1898.)

THE present work is perhaps, in point of thoroughness of treatment, the best on this subject we have yet seen. It is written, not as an introduction to a hitherto unknown subject, but as an account of a well-established branch of engineering.

In this country, the comparative absence of water-power near our industrial centres, and the resulting small demand for long-distance power-transmission, has led to a relative indifference to this important subject. What limited field for such transmissions does exist, seems at present to arise rather from the vastness of our towns, than from the existence of available water-power.

The economy in electrical transmissions of energy, which accompanies the employment of high-pressure currents, has led to the use of the readily-transformed alternating current. And while, as M. Rodet remarks, electric lighting can be carried out equally well with single-phase currents as with polyphase, yet, for purposes of motive power, the absence of a good motor to run on single-phase circuits, and the excellence of the rotary field motor, necessitates the use of polyphase currents by which alone the rotary magnetic field can be produced.

Starting with an historical summary, M. Rodet deals successively with generator, line, and motor. While keeping the essentially practical aspect of his subject in view, and citing from time to time, by way of illustration, the conditions of actual installations, the author, nevertheless, does not hesitate to launch into ample theoretical investigations where he deems these called for. At the conclusion of the main part, a short but interesting chapter on meters for polyphase currents is given.

Of more general interest, however, are the descriptions of installations. These form a most interesting conclusion to the work. We observe that just one quarter of the examples selected by the author as types for description are two-phase transmissions; the rest are three-phase installations, and these include several of importance in south-west France.

The illustrations are for the most part simple and clear. English readers will feel the lack of an alphabetical index, and would prefer to have titles to the illustrations. The work should, however, prove of great value to engineers who wish to make a special study of polyphase current machinery. D. K. M.

My Horse; My Love. By Sarah Buckman-Linard. Pp. xii + 227. (London: T. Fisher Unwin, 1898.)

IT is a little difficult to classify Mrs. Buckman-Linard's book. It is not a treatise, nor a text-book, nor a story. It is written in a conversational style not always easily followed. Here is a sentence which demands exceptional powers of perception:—"In some the odour is perceptible to themselves only, while in others it is such a powerful means of defence as to make the pursuing victim wish he had never been born, which floods cannot drown nor fires quench, if any part escape, and only six feet of earth can extinguish" (p. 22). The book is divided into chapters, but the title of the chapter is little indication of its contents; *e.g.* Chapter ii. is headed "Facilities for Breeding in America," and after a few generalisations on the subject mentioned in the title the following questions are dealt with:—Is it possible that human beings have the same diseases as horses? Are the symptons easily recognised (reference is made to the symptons of glanders)? Is it possible to mend a broken leg? Chapters are also included on jockeys, the Derby day, and training. At the same time there is a quantity of information about the horse, scattered here and there in the volume; and if it had been systematically arranged in half the compass, it might have proved useful.

Matter, Energy, Force and Work. By Silas W. Holman. Pp. xiv + 257. (New York: The Macmillan Company, 1898.)

PROF. HOLMAN here addresses students and teachers of physics and chemistry on the concepts and definitions of physical science. Some knowledge of the experimental side of the subject and its phenomena and laws is assumed, and the logical expression and sequence of the ideas put forward should prove of great value to engineers, and others who have to apply physical and chemical knowledge, in enabling them to think clearly when dealing with the fundamental ideas on which all successful practice must be based. The book is divided into two parts: the first is concerned with a consideration of matter, motion, energy, force and work; the second with the kinetic theory of gases, Le Sage's theory of gravitation, the vortex-atom theory, and the nature of energy and matter. Prof. Holman describes the first part as "a sporadic attempt at clear, consecutive setting forth of individual thought," the second as intended "to give more concreteness to the concepts than could properly be introduced into the first part." The volume deserves to be widely read.

The Way the World Went Then. By Isabella Barclay Pp. xiv + 153. (London: Edward Stanford, 1898.)

THE author of this volume did not live to see it through the press, and the MS. has been edited by two lady friends, who contribute the preface and a summary of three pages, in which they state what they think the author would have included in the second part of her work had she lived. It would be unkind to subject a volume produced under these conditions to severe criticism, and we will merely say that, although the book affords evidence of a fervent desire to present the earth's history in a simple and interesting manner, it is seriously misleading in many matters of fact. and unequal in treatment. The volume is daintily bound, and has some attractive illustrations.

LETTERS TO THE EDITOR.

Fourier's Series.

IN reply to Mr. Love's remarks in NATURE of October 13, I would say that in the series

$$y = \sin x + \tfrac{1}{2}\sin 2x + \;.\;.\;.\; + \frac{1}{n-1}\sin(n-1)x + \frac{1}{n}\sin nx,$$

in which $\frac{1}{n}\sin nx$ is the last term considered, x must be taken smaller than π/n in order to find the values of y in the immediate vicinity of $x = 0$.

If it is inadmissible to stop at "any convenient nth term," it is quite as illogical to stop at the equally "convenient" value π/n. ALBERT A. MICHELSON.

The University of Chicago Ryerson Physical Laboratory, Chicago, December 1.

I SHOULD like to add a few words concerning the subject of Prof. Michelson's letter in NATURE of October 6. In the only reply which I have seen (NATURE, October 13), the point of view of Prof. Michelson is hardly considered.

Let us write $f_n(x)$ for the sum of the first n terms of the series

$$\sin x - \tfrac{1}{2}\sin 2x + \tfrac{1}{3}\sin 3x - \tfrac{1}{4}\sin 4x + \&c.$$

I suppose that there is no question concerning the form of the curve defined by any equation of the form

$$y = 2f_n(x).$$

Let us call such a curve C_n. As n increases without limit, the curve approaches a limiting form, which may be thus described. Let a point move from the origin in a straight line at an angle of 45° with the axis of X to the point (π, π), thence vertically in a straight line to the point $(\pi, -\pi)$, thence obliquely in a straight line to the point $(3\pi, \pi)$, &c. The broken line thus described (continued indefinitely forwards and backwards) is the limiting form of the curve as the number of terms increases indefinitely. That is, if any small distance d be first specified, a number n' may be then specified, such that for every value of n greater than n', the distance of any point in C_n from the broken line, and of any point in the broken line from C_n, will be less than the specified distance d.

But this limiting line is not the same as that expressed by the equation

$$y = \underset{n=\infty}{\text{limit}}\; 2f_n(x).$$

The vertical portions of the broken line described above are wanting in the locus expressed by this equation, except the points in which they intersect the axis of X. The process indicated in the last equation is virtually to consider the intersections of C_n with fixed vertical transversals, and seek the limiting positions when n is increased without limit. It is not surprising that this process does not give the vertical portions of the limiting curve. If we should consider the intersections of C_n with horizontal transversals, and seek the limits which they approach when n is increased indefinitely, we should obtain the vertical portions of the limiting curve as well as the oblique portions.

It should be observed that if we take the equation

$$y = 2f_n(x),$$

and proceed to the limit for $n = \infty$, we do not necessarily get $y = 0$ for $x = \pi$. We may get that ratio by first setting $x = \pi$, and then passing to the limit. We may also get $y = 1$, $x = \pi$, by first setting $y = 1$, and then passing to the limit. Now the limit represented by the equation of the broken line described above is not a special or partial limit relating solely to some special method of passing to the limit, but it is the complete limit embracing all sets of values of x and y which can be obtained by any process of passing to the limit.

J. WILLARD GIBBS.

New Haven, Conn., November 29.

FOURIER's series arises in the attempt to express, by an infinite series of sines (and cosines) of multiples of x, a function of x which has given values in an interval, say from $x = -\pi$ to $x = \pi$. There is no "curve" in the problem. Curves occur in the solution of the problem, and there they occur by way of illustration. There are two sorts of curves which occur. In the first place, taking $\phi(x)$ as the function to be expressed by the series, and $f(x)$ as the sum of the series, we have the curves $y = \phi(x)$ and $y = f(x)$, the graphs of the two functions. These coincide wherever the series expresses the function; but, if the function $\phi(x)$ is one which cannot be expressed by a Fourier's series for all values of x in the interval, the curves do not coincide throughout the interval. In the second place, taking $f_n(x)$ as the sum of the first n terms of the series, we have the family of curves $y = f_n(x)$, the graphs of $f_n(x)$ for different values of n. As n increases the graphs of $f(x)$ and $f_n(x)$ approach to coincidence in the sense that, if any *particular value* of x is taken, and any small distance d is specified, a number n' may then be specified such that for every n greater than n', the difference of the ordinates of the two curves is less than d. But this is not the same thing as saying that the curves tend to coincide geometrically, and they do not in fact lie near each other in the neighbourhood of a finite discontinuity of $\phi(x)$. It is usual to illustrate the tendency to discontinuity of $f(x)$ by noting the form of the curve $y = f_n(x)$ for large values of n, but the shape of this curve always fails to give an indication of the sum of the series for the particular values of x for which $\phi(x)$ and $f(x)$ are discontinuous. This is the case in the example cited by Prof. Willard Gibbs, where all particular values between $-\pi$ and π are equally indicated by the curve $y = f_n(x)$, but the sum of the series is precisely zero.

May I point out that there is some ambiguity in the expression "the limiting form of the curve" used by Prof. Willard Gibbs? Taking his example, it is quite true that n' can be taken so great that, for every n greater than n', there is a point of C_n within the given distance d of any point on the broken line, but this statement is not quite complete. It is also true that a number n can be taken great enough to bring the point of C_n on *any assigned* ordinate within the given distance d of its *ultimate position* on the broken line, but it is further essential to observe that no number n can be taken great enough to bring *every* point of C_n within the given distance d of its ultimate position on the broken line. The number n which succeeds for any one ordinate always fails for some other ordinate. Suppose, to fix ideas, that we take a point on C_n for which $y = 1$, and x is nearly π, so that $\pi - x$ is less than d, and keeping x fixed, observe how y changes when n increases; it will be found that, for values of m very much greater than n, the ordinate of C_m, for this x is very nearly π, and we can in fact take m great enough to make this ordinate lie between π and $\pi - d$. In words, the representative point, which begins by nearly coinciding with a point on a vertical part of the broken line, creeps along the line, and ends by coinciding with a point on the oblique part of the broken line. This will be the case for every value of x, near $x = \pi$, with the single exception of the value π. Thus, in the passage to the limit, every point near the vertical part of the broken line disappears from the graph, except the points on the axis of x. This peculiarity is always presented by a series whose sum is discontinuous: in the neighbourhood of the discontinuity the series does not converge uniformly, or the graph of the sum of the first n terms is always appreciably different from the graph of the limit of the sum.

In this way the graph of the sum of the first n terms fails to indicate the behaviour of the function expressed by the limit of this sum, and we may illustrate the distinction between the two, as Prof. Willard Gibbs does, by considering the intersections of the graph with lines parallel to the axis of x. Keeping y fixed, say $y = 1$, we may find, in his example, a number n, so that there is a corresponding value of x differing from π by less than d, and then, allowing n to increase indefinitely, we shall get a series of values of x, having π as limiting value. But this limiting value is *not attained*. In Prof. Willard Gibbs's notation, the equation $2f_n(x) = 1$ has a root near to π when n is great, and n can be taken so great that the root differs from π by less than any assigned fraction; but the equation

$$\underset{n=\infty}{\text{limit}}\; 2f_n(x) = 1$$

has no real root. In fact Prof. Willard Gibbs's "limiting form of the curve" corresponds to limits which are not attained: but the limiting form in which the vertical portions of the broken line are replaced by the points where they cut the axis of x corresponds to limits which are effectively attained. It is the

latter limiting form, and not the former, which is the graph of the sum of the Fourier's series.

The matter here discussed is perhaps that referred to by Prof. Michelson in Nature of October 6, but I did not understand his letter so. In regard to his present communication, I agree with him if he means that it is just as necessary, in tracing the part of the curve C_n near the vertical part of the broken line, to take a particular value of n, as it is to keep x within a narrow range of values corresponding to n. But this admission is not equivalent to admitting that an infinite series may be summed by stopping at any particular term. Rather it confirms the conclusion, explained above, that the graph of the sum of the infinite series contains no vertical line.

December 22. A. E. H. Love.

The Schmidt-Dickert Relief Model of the Moon.

The present location of the Schmidt-Dickert relief model of the moon is probably not generally known in Europe. Webb's "Celestial Objects for Common Telescopes" (edition of 1896) states that the model is in Bonn, and this impression probably generally prevails. As a matter of fact the model has been for about twenty years in America. It has been on exhibition only at rare intervals during the time, however, and hence has been lost sight of. By a disposition recently made of it, it has fortunately become available to students of science and the public generally. Through the generosity of Mr. Lewis Reese, of Chicago, it has been presented to the Field Columbian Museum, and is now installed in this institution.

The model is in the form of a hemisphere about nineteen feet in diameter, and upon its surface are shown, in proportional relief, over 20,000 distinct localities. In his original description, Dr. Schmidt, the eminent selenographer, states that the details were based on the chart of Beer and Madler, but many features were added from his own observations. He also states that he carefully guided and watched over the work of construction, and with his own hand tested its correctness in all essential particulars. These statements give sufficient assurance of the accuracy of the model, and the confidence with which it may be studied. It is probably the best substitute extant for a trip to the moon. Oliver C. Farrington.

Field Columbian Museum, Chicago, December 12.

Maxwell's Logic.

In a paper on the experimental verification of Ohm's law (Brit. Assoc. Report, 1876), Maxwell makes the following statement.

"Assume that the resistance of a given conductor, at a given temperature, is a function of the strength of the current. Since the resistance of a conductor is the same for the same current, in whichever direction the current flows, the expression for the resistance can contain only even powers of the current."

It seems to me that such an argument is not applicable to a case of this kind.

Consider, for example, the flow of a liquid along a capillary tube. We might define the resistance of any portion A B of such a tube to be the ratio of the difference of pressure between A and B to the quantity of liquid flowing across any section in unit time.

Now would it not be equally legitimate to apply the above reasoning to this case, and prove that the resistance of a capillary tube could not vary as the first power of the velocity? Although of course, there may be no physical analogy between flow of liquid and electric current. Again, imagine a uniform wire A B along which a current of electricity is flowing, the ends A and B dipping into mercury cups (say). Now, instead of reversing the direction of the current, let the wire be turned end for end. Surely there is no difference between this and the previous case, and yet the current in the wire is reversed.

John Lister.

Royal College of Science, London, South Kensington, S.W., December 12.

LORD IVEAGH'S GIFT.

The announcement, made in the daily papers last week, of Lord Iveagh's intention to devote the princely sum of 250,000*l.* to the endowment and promotion of bacteriological research in England, has arrested the attention of the country and of every class of the community. The humane and enlightened sentiments that have actuated Lord Iveagh, and the liberal manner in which these have been given effect, constitute a unique claim to the gratitude and appreciation of his fellow countrymen.

The distinction of such gifts had hitherto remained, and appeared likely to remain, the prerogative of America and American millionaires. The open-handed liberality of Rockfeller, Armour and many others has enabled the United States to provide endowment for research and to equip laboratories on a scale of completeness unattempted in the mother country, whilst on the continent the scientific worker has long found encouragement and support in State-aided institutions. The result has been that in bacteriological as well as other branches of inquiry England has lagged behind.

Lord Iveagh's decision to devote the proposed endowment to an Institute that had been endeavouring with inadequate means to carry out the work with which he sympathises, has met with widespread approval. It is now seven years since the British Institute of Preventive Medicine was founded with the view of establishing in England a national home for bacteriological work and inquiry. The scheme received its inception at a meeting held at the Mansion House, and from the first obtained the sympathy and support of eminent men of science and members of the medical profession. A fund was raised at the same time to provide poor patients with the means of proceeding to Paris to undergo the Pasteur treatment for rabies. This fund is still administered by the Institute, and no year has passed without several claims being made for its help.

The new Institute was duly incorporated under the Companies Act, and a Council was appointed to further its objects—first amongst these being investigations in connection with the prevention and treatment of infectious diseases. The Council elected represented all branches of scientific work likely to be benefited by bacteriological investigation, and the work of the Institute was thus at the outset wisely placed on the broadest possible basis.

The services of Lord Lister, as Chairman of Council, and of Sir Henry E. Roscoe, as Hon. Treasurer, have been of inestimable value to the fortunes of the Institute. The liberality of the Grocers' Company and of private individuals, along with a handsome donation from the Trustees of the late Mr. Berridge, enabled the Council to take steps to acquire a building site. A favourable site was acquired on easy terms at Chelsea, through the liberality of the Duke of Westminster, and building operations were commenced. The amalgamation of the College of State Medicine with the Institute was effected at the same time, and in this way temporary premises were acquired at Great Russell Street for the initiation of work. The Institute occupied these premises during four years, and the various departments to be established at Chelsea were successfully organised through the efforts of a small but zealous staff. The discovery by Behring of the antidiphtheria serum, and its beneficial use abroad, led the Institute to undertake its preparation for the first time in this country. A farm was rented at Sudbury, near Harrow, and provided with laboratory and stabling accommodation, and the preparation of the serum commenced. A public appeal was made for funds, and a sum of money, sufficient to pay the initial expenses of the new departure, was raised. The work of the antitoxin department of the Institute has since then greatly expanded—the antistreptococcus and antitetanus serum being now prepared, as well as the diphtheria serum, and placed at the disposal of medical men. The Institute also undertook the preparation of tuberculin and mallein for diagnostic purposes.

The work undertaken in the antitoxin and other departments proved a serious drain on the resources of the

Institute, and the Council, after careful consideration of the financial position, most reluctantly decided to abandon completion of the original plan of the Institute, and to leave it an unfinished building. The plans were accordingly modified by the architect, and a portion of the building was proceeded with and completed last year. The Institute took possession of the new building in May of this year, when the fittings of the main laboratories were completed. The fittings of the building, as it at present stands, are now all but completed. A most promising start has been made, and the facilities for investigation and instruction are being widely taken advantage of.

The Jenner Memorial Committee decided last autumn to transfer any funds it might receive to the Institute. The Council, in view of this, decided to alter the title to the Jenner Institute, and in this way to commemorate permanently the memory of Jenner and his work. The necessary legal formalities were completed on the 6th inst., and the Institute from that date continued its work as the Jenner Institute of Preventive Medicine.

Lord Iveagh was a generous contributor to the Jenner Fund. At the same time, the financial outlook was by no means rosy—working expenses had greatly increased at Chelsea; the salaries of the staff were insufficient, and subscriptions were coming in slowly. These facts were causing serious anxiety to those responsible for the management of the Institute. On December 20, Lord Lister was able to communicate to the Council of the Institute Lord Iveagh's munificent offer, along with the conditions attached to it. The public announcement of this noble gift and its cordial acceptance was made by Lord Lister and Sir Henry Roscoe in a letter to the press on the 23rd inst. The letter states that the bequest is given on the condition that in future the control and mangement of the affairs of the Institute be placed in the hands of a new Board of seven Trustees, three of the seven to be chosen by the Council of the Institute, three by the donor, and one by the Council of the Royal Society.

It is further proposed that the building of the Institute at Chelsea be enlarged, and the original scheme of the same completed; that the sadly inadequate salaries of the director and other members of the staff be increased, and that valuable scholarships and studentships in connection with the Institute be established. There are, of course, many details to be arranged and settled; but it will be seen that the scheme is far-reaching, comprehensive and carefully thought out, whilst the conditions attached are by no means onerous.

The rare modesty of the donor will not, we feel sure, prevent the realisation of the general wish that his name be gratefully and permanently associated with the beneficent work he is about to inaugurate.

Amongst the first results will be, as desired by Lord Iveagh, the completion of the Chelsea building; and the foundations being already laid, this can be proceeded with without delay. The provision to be made for an adequate emolument to the members of the staff, along with the establishment of scholarships and studentships, will furnish an incentive and encouragement hitherto lacking to workers in this field. Many promising researches have of necessity been postponed at the Institute, through the difficulty in finding sufficient assistance to carry them out. Large questions can now be attacked, and the time ungrudgingly given to their elucidation by properly trained experts. A small stream of research work has issued from the Institute; this will be widened and deepened. The students, who have come from all parts of the country and the empire for instruction in bacteriology and preventive medicine, will increase in numbers with the unique facilities that will be placed at their disposal.

The establishment of a British and Imperial Institute of Bacteriology is now within a measurable distance of realisation. The present building at Chelsea contains, amongst its main features, the following departments:—(1) The bacteriological laboratories, devoted to bacteriological investigation and instruction in connection with medicine, public health, and the pathology of disease. (2) The chemical and water laboratories, dealing mainly with water, soil, air, and food, in their hygienic aspects. (3) The Hansen laboratory, dealing with the practical applications of bacteriology to agriculture, brewing, dairy and other industries. (4) Research rooms for advanced workers, and museum and lecture theatre. (5) The requisite facilities for experimental work and investigation in connection with the causation and prevention of disease.

This work will now be placed on a sure and permanent basis, and the Institute will be brought fully abreast with the best foreign laboratories devoted to bacteriology. Through Lord Iveagh's munificence, the objects for which the Institute was established can now be developed on a scale commensurate with their importance.

ALLAN MACFADYEN.

GEORGE JAMES ALLMAN.

IN George James Allman, who died at his residence, Ardmore, Parkstone, Dorset, on Thursday, November 24, at the advanced age of eighty-six, zoological science has lost a zealous and most accomplished worker, the world a great man. He was born at Cork in 1812, being the eldest son of Mr. James Allman, of Bandon, in that county, and was educated at the Belfast Academical Institution, originally for the Bar. As with so many others born to science, he early drifted into paths most congenial to his nature, and accordingly graduated in Arts and Medicine in the University of Dublin. He became a member of the Royal College of Surgeons, Ireland, in 1842, and a Fellow in 1844, and took his M.D. (University, Dublin) and (University, Oxford) in 1847. He from early days displayed a passionate devotion to the study of organic nature, and so highly was he esteemed that during the year of his graduation he was appointed Regius Professor of Botany in the Dublin University. Here the late Professor of Geology, Beete-Jukes, was one of his most intimate friends. Thus embarked on a career of scientific work and investigation, Allman gave up all thought of the medical profession, and ten years later resigned the Dublin chair for that of Regius Professor of Natural History in the University of Edinburgh, with which was incorporated the Keepership of the Natural History Museum, and these combined offices he held until 1870, when he retired into private life. In Edinburgh he was no less a favourite than in Dublin; and his lifelong friendship with the late Lord Playfair, Lord Shand, and many of his most brilliant contemporaries began in that good old town, where he built himself the house in Manor Place, where his clever and charming wife made so happy a home for himself and his friends. During his period of activity in the two great capitals named, Allman laboured with untiring zeal, ever intent on the progress of science and the best interests of those who came under his charge. On his retirement, first to London and afterwards to Parkstone (Dorset), his energy never flagged, the most conspicuous change in his actions being the substitution of the personal care of a small but very picturesque estate of five or six acres at Parkstone, having great possibilities for a naturalist and lover of outdoor life, for the more fatiguing duties of the reception- and drawing-room, encumbent upon him in his professorial capacity. Not that Allman despised the latter, for, on the contrary, while in Edinburgh especially, his drawing-room was the rendezvous of the cultured, drawn together by

the personal charm and gifted influence of his wife, to whom he owed much of his popularity and success. Playfair and Shand may be named among the more regular attendants at these gatherings; but Allman, a born field-naturalist, full of vigour, yearning for the open, found his greatest contentment in the field, and in dredging expeditions, in which both in Ireland and Scotland he took the most ardent interest.

As a worker Allman was untiring and prolific, and between the years 1835–1873, apart from his monographs, which are alone monumental, he produced considerably over 100 papers, mostly to be found in the publications of the Royal and other learned Societies of London, Dublin and Edinburgh, in the *Annals and Magazine of Natural History*, and elsewhere; and while in later years he became less prolific, we find him working to the last, and as late as 1897 contributing (Phœnix-like to the younger generation of naturalists) a paper (*Jour. Linn. Soc. Zool.*, vol. xxv. p. 517) on the hybernaculum of the common snail, embodying a most interesting observation overlooked, because always present, by the multitude who had yearly dissected the animal. Many of the miscellaneous papers by which he will be best remembered are "Reports," such as those of the "Porcupine"; and by association with Bowerbank, the elder Carpenter, Hancock, Hincks, Gwyn Jeffreys, Wyville Thomson, and others, he will be ranked among the earlier pioneers in the study of the marine zoology of Britain, whom he was almost the last survivor. His work upon the freshwater forms, especially as involving the Polyzoa, and his long intimacy with his great personal friend Busk, is little less noteworthy and historically important. Contemporary of Owen, friend of Huxley, correspondent of the elder Agassiz, truly does it seem that with his decease a link with the historic past has been lost; but among giants who survive him Hooker remains, as one who, with Alex. Agassiz, McIntosh, and Norman, has been his counsellor and friend.

Allman was as versatile as voluminous and proficient, since his papers deal with well-nigh all the great groups of animals, between and including the Protozoa and Mammalia. Recent and fossil forms had for him a like interest; and to have passed as a solid worker from the study of the arteries of the Armadillos through that of a fossil Seal, an Ophiurid, and the Graptolites, to the Peridiniaceæ, working the meanwhile at all sorts of Invertebrates, at questions physiological, anatomical, developmental, and taxonomic, taking by the way the study of parasitism, fermentation, and even of snow-crystal formation, is to have established a record worthy of the emulation of the serious science student. Allman's first paper was a botanical one, "On the Mathematic Relations of Forms of Cells of Plants," and it is worthy of note that in this he in a sense anticipated one of the most recent among our biological departures. He is to be seen at his best as a casual investigator of his time, in his papers on the development and palæontology of the Crinoids and on the Potamogale, a young specimen of which he described. His greater reputation, however, rests upon his monumental investigations into the classification and morphology of the Cœlenterata and Polyzoa, upon which he has left a mark for all time. His first paper on the Polyzoa appeared in 1843—his great monograph on the fresh-water members of the class in 1856; while his first paper on the Hydrozoa was published in 1844, and his epoch-making "Gymnoblastic or Tubularian Hydroids" was completed in 1872. During the thirteen years thus apparently occupied in the preparation of the first and the twenty-eight in that of the second, he was active in the production of numerous papers dealing with both groups of animals, and on the Cœlenterata alone he published up to the period named close upon fifty papers all told. His original descriptions of *Rhabdopleura*, *Myriothela*, *Limnocodium*, sufficient in themselves to have made him famous, stand conspicuous in contemporary scientific literature, and in his reports upon the Hydroids of the *Challenger* expedition and on the Hydroids obtained during the exploration of the Gulf Stream under the direction of the United States Government, his work will remain memorable in the later progress of marine zoology. Of his *magnum opus* the "Gymnoblastic or Tubularian Hydroids," it may be said that its appearance marked an epoch in the history of the scientific investigation of the Cœlenterata. This glorious work, pre-eminent among the magnificent monographs of the Ray Society, came as a revelation to the zoologists of the time. Its classical companions, the "British Naked-eyed Medusæ" of Forbes and the "Oceanic Hydrozoa" of Huxley, had paved the way for its appearance, by extending our knowledge and simplifying our conceptions of the complex structure of the Colonial Hydrozoa. Johnston's "British Zoophytes" was still a leading work of reference on the group, and Reay Greene's "Manual of the Cœlenterata" had enticed to the study of the class many a student who might have strayed into other paths. Allman's monograph, with its 400 pages of text, clear, comprehensive, and logical, with its twenty-three exquisite coloured plates (faithful copies of their author's original drawings, which even in those days had to be engraved in Germany), came as the fulfilment of a great promise. Its first part, dealing in general terms with the morphology, physiology, and chorology of the Hydrozoa, with its masterly "Glossology," ranks among the most perfect and philosophic of all modern zoological treatises. The exquisite beauty of its illustrations, in respect to which it vies with other scientific works of its time, is no less remarkable than the consummate pains bestowed upon its pages. It is a perfectly ideal treatise, finished and artistically complete in all its parts, and it is not too much to say that it revolutionised and placed upon a solid foundation for all time our knowledge of one of the most perplexing of nature's handiworks. Its influence on contemporary investigation in zoology has been far reaching, and had its author achieved nothing beyond it he would have left an ineffaceable mark upon time. Much of the work which constitutes its foundation was done in Irish waters, which thereby became classical ground in the investigation of the British Cœlenterates, so successfully continued at present for the Actinozoa by Haddon and his pupils and associates, and for the Hydrozoa by Brown and the Misses Delap.

Beyond his professorial and research work, Allman was active in the popularisation of zoology. He was among the earlier supporters of the British Association, his first papers having been read before it. He in 1873 presided over its Biological Section, and was in 1879 President of its Sheffield meeting. He was in 1855 appointed one of the Commissioners of Scottish Fisheries, which post he held until the abolition of the Board in 1881, and in 1876 was one of those selected to inquire into the working of the Queen's Colleges in Ireland. During the years 1874–1881 he was President of the Linnean Society, succeeding Bentham. In this capacity he was not altogether a success as a chairman; but by his solicitations on behalf of the Society—and his presidential addresses—he did much to further its welfare. Those on the Protozoa, delivered consecutively during his first two years of office, which, together with his remarkable monograph on the fresh-water Medusa (*Limnocodium Sowerbyi*), which also appeared in the Society's Journal, admirably illustrated by woodcuts from the facile hand of Ferrier, amply testify to his desire to be of use to the Fellows of his Society, so adequately expressed in the peroration to his 1877 address.

Allman served on the Councils of the Royal Societies

of London and Edinburgh, and of the Royal Irish Academy, and he officiated as examiner in natural history for the Queen's University of Ireland, the University of London, the army and navy and Indian Medical Service, and for the Indian Civil Service. He was in 1854 elected a Fellow of the Royal Society, and in 1873 received the Society's Royal Medal. He was in 1877 awarded the Brisbane Gold Medal of the Royal Society of Edinburgh, and in 1878 the Cunningham Gold Medal of the Royal Irish Academy, while in 1896 he received the Gold Medal of the Linnean Society he had served so well. In 1879 there was conferred upon him the Hon. LL.D. of the University of Edinburgh.

On his retirement into private life Allman settled in Dorsetshire, on the genial slope of the ridge overlooking Poole Harbour, there to devote himself to his outdoor pursuits and to horticulture, which was with him a passion; and it is not a little remarkable that he, who in earlier years had committed himself to the views concerning man's place in nature expressed in a short paper he in 1889 read before the Royal Society of Edinburgh, should have had for friend and neighbour in the closing years of his life Alfred Russel Wallace, whose views on Darwinism applied to man were so akin to his own. But it is not in this interesting association of these two great men that the Dorsetshire village will alone be hallowed ground to the zoologist of the future, for it also bears testimony to Allmann's loving devotion to his wife, in a manner which associates her directly with his triumphs and pursuits. For her use he therein had built, midst his beautiful garden, a substantial brick house, with a tiled terrace so arranged that she might sit and read and talk to him while occupied with his favourite pursuits. The garden itself is a perfect picture of undulating beauty, covering an area of some five or six acres, its owner having been particularly careful to avoid all suggestion of suburbanism in its design. Bamboos, a Grumera, rhododendrons of great rarity and value, carefully hedged around for protection against cold and wind, rivulets whose banks are flanked by many a botanical treasure, a stream here, the occasional pollution of which filled him with agony expressed in strongest remonstrance—a pond there, the inhabitants of which were individually the care of its owner—the whole a little paradise—one pictures the grand old man, resolute to the last, seated on his favourite tree stump or rustic seat, as for hours he used to watch the unfolding of the tender bud or the ripple of the innocent streamlet. Every plant was known to him, every label bore his handwriting, and all around was the special object of his tender care.

Great as was Allman's love of nature and freedom, the distinguishing features of his character were his manliness and gentlemanly consideration for others, and in combination with an artistic temperament amounting to the poetic, these gave to his individuality a rare charm. In testimony to the former combination, there stands in his drawing-room, foremost among the treasures he prized most highly, a clock, presented to him on the occasion of his retirement from the Edinburgh chair, which bears the following inscription:

To George J. Allman, Esq., M.D.
Professor of Natural History
In the University of Edinburgh,
This Timepiece is respectfully presented
By a few students
Now and formerly attending his lectures,
As a small mark of their sincere regard for him
AS A GENTLEMAN,
And their admiration of his talents
And ability as a naturalist.
29 July, 1870.

His poetic fancy had led him in his later years to commit his thoughts to verse, which it was one of the concluding ambitions of his life to see in print. But in vain—since the small volume of his poems, which he had printed for private circulation, only reached the house on the day of his decease. As to the literary merits of this opinions might differ, but his verses soar above the peevish Heineësques of Albrecht and the laboured mnemonics of Anderson, two among modern zoologists who have been constrained to write poetry, and they have a special value in that they are the expression of the poetic effusions of his mind prompted by actual work in the field and on the water which made him famous, and of which they are largely descriptive. None other than Johannes Müller, the father of comparative anatomy, has remarked: "Die Phantase is ein unentbehrliches Gut"; and the thought arises that the discipline of biological science soars above that of the more rigid and strictly mathematical in the extent to which it stimulates the imagination, one of the highest of the intellectual faculties.

Allman endeavoured to work to the last, and to the end his brain power remained perfect and his sight and hearing good. It is extraordinary how his eyesight remained practically unimpaired by his constant microscopic work extending over some seventy years. Though latterly weakened by asthma, he would day by day sit at his favourite table and write, and he leaves unfinished a book apparently intended for publication in one of the scientific series. His wife predeceased him in 1890, and he had no family; but he was especially fortunate in the loving care of nieces and others who had learned to take an interest in his life work, and who afterwards made his home bright and happy. He had this autumn planned some considerable additions to the garden of which he was so fond, dedicating a portion of it to a favourite grand-niece, "Erica," and there can be little doubt that he never imagined himself failing. But a few hours after what proved to be a farewell visit to his dearly beloved plants, he died quietly in his arm-chair. A steady loss of muscular power throughout his whole system during the past few months apparently extended somewhat suddenly to the heart, and took from the world of science an earnest worker, a man in whom the artistic and philosophic temperament were exceptionally combined, and whose name and influence for good will endure. G. B. H.

DR. H. W. VOGEL.

EVERY one interested in photography—and in these days who is not?—must deeply regret that so eminent a worker as Dr. Vogel has passed away. He was one of the pioneers in the band of investigators in what may, perhaps, be called the second period of the development of photography, dating from the time of the daguerreotype to the introduction of gelatine dry plates. When Fox Talbot and Daguerre made known their wonderful methods of making nature draw her own pictures, he was a lad of six or seven years of age, and it was thirty-four years after this that Dr. Vogel announced his discovery that, by the use of certain colouring matters, it was possible to make a photographic plate sensitive to other colours than those to which it had previously been considered as sensitive. This discovery was of so radical a nature that a considerable number of eminent experimentalists were quoted as having failed to corroborate the observation, and the general idea at the time seemed to be that Vogel's announcement was due to an error in his work. At the present day there is no need to enlarge upon the importance of colour sensitisers, for, practically speaking, the whole art of the correct monochromatic rendering of colours by photography, and of the various indirect methods of producing pictures in natural colours by photographic means, are founded upon their use. The fact that it is rather an increase of sensitiveness than the actual conferment of sensitiveness that is effected, and that Dr. Vogel's theory of the action has not commended

itself to other workers in the same field, are only matters of detail that in no way affect the facts established by him.

Dr. Vogel's activity was shown in almost every branch of photography, and in many of its applications. His astronomical work, especially in connection with eclipses of the sun, is well known. The existence and prosperity of the Imperial Technical High School of Photography, at Berlin, is the best of evidence of his work as a teacher. His "Handbook of Photography," "Practical Spectrum Analysis," and other treatises, will long remain as useful guides. The *Photographische Mitteilungen*, which he established in 1864 and conducted himself until quite recently, and the position that at one time he took up as correspondent of other technical papers, show how much he valued and worked for current photographic literature. There are few men who have done such varied and lasting work in connection with photography as Dr. H. W. Vogel.

NOTES.

WE notice with much regret the announcement that Prof. A. A. Kanthack, professor of pathology in Cambridge University, died on Wednesday, December 21, at the early age of thirty-five.

THE French Société d'Encouragement pour l'Industrie Nationale has received a gift of twenty thousand francs from M. Gilbert (of Givet), to be used for the advancement of French industries.

MR. FREDERICK G. JACKSON, the leader of the Jackson-Harmsworth Arctic expedition, has received a knighthood of the first class of the Royal Order of St. Olaf from King Oscar of Sweden and Norway.

A BIOLOGICAL Section for Agriculture and Forestry has been established in connection with the Imperial Sanitary Bureau at Berlin. Dr. Freiherr v. Tubeuf (of Munich) has been appointed botanist, and Dr. J. Behrens (of Carlsruhe) bacteriologist to the Section.

THE death is announced of Mr. John Barrow, F.R.S., at the age of ninety-one. He took an active part in promoting the search for Sir John Franklin, and was the author of several books of travel and descriptions of glaciers in the Alps. He was elected a Fellow of the Royal Society so far back as 1844.

THE following gentlemen have been elected corresponding members of the Zoological Society:—Dr. Ludwig Heck, of the Zoological Gardens, Berlin; Mr. William T. Hornaday, of the Zoological Park, New York, U.S.A.; Dr. Herman von Ihering, of the Musen Paulista, St. Paulo, Brazil; and Prof. Louis von Méhely, of the National Museum, Budapest.

WE learn from *La Nature* of December 24, that a mountain observatory has been erected at Mont Mounier, the highest point of the Maritime Alps, at 2816 metres above the sea-level, and about 90 kilometres north-west of Nice. The cost of the establishment has been defrayed by M. Bischoffsheim, a member of the Institute, who also endowed the Nice Observatory. The mountain station is connected by telephone with the telegraphic station at the village of Beuil, and meteorological observations are regularly made by M. Maynard. As the position is all that can be desired for the purpose, we may hope for some valuable results in connection with those obtained at the Nice Observatory. During the frosts of winter the temperature at the upper station falls to about 36° F. below the freezing point.

A RECENT number of the *Lancet* contains a paper by Mr. A. F. Stanley Kent, entitled "The Specific Organism of Vaccinia." The author has found a diplo-bacillus present in large numbers in the deeper parts of the vesicle. This organism he has succeeded in cultivating in artificial media, and has been able to produce, by its inoculation into animals, vesicles "indistinguishable from those produced in the ordinary course by vaccination with current lymph." Mr. Kent further states that animals which have been thus inoculated subsequently give no reaction when revaccinated with active lymph. Many investigators have been drawn into this field of research, but hitherto the difficulties of deciding the claims of so many rival candidates have proved insuperable. It will be important to have Mr. Kent's results repeated and confirmed by other workers, and there can be no doubt that his suggestive and promising achievement will give fresh energy to the conduct of experiments in this direction.

THE Shanghai Meteorological Society has issued its report for the years 1896 and 1897. The headquarters of the Society is at the Zi-ka-wei Observatory, of which the Rev. A. Froc, S.J., is Director. The observatory receives daily two or three telegrams from forty-two stations, including those from Corea, Japan, Formosa, and the Phillipines, and issues storm warnings to several ports. The present report contains a discussion of two notable typhoons which occurred on September 9 and 29, 1897. The first of these was of unusual violence; it fell like a thunderbolt upon the city of Yokohama, and caused considerable havoc there and in the neighbouring districts. The storm struck the steamship *Empress of India* in lat. 33° 30′ N., long. 137° 5′ E., on the night of September 8–9, and in the course of two hours the barometer on that vessel fell 1·25 inch, and in less than forty minutes the mercury again rose 1·40 inch. During part of its course the storm travelled at a rate of over fifty miles an hour.

THE effect of approaching storms upon song birds is the subject of an interesting contribution by Mr. C. E. Linney to the U.S. *Monthly Weather Review*. It appears that during the night of August 15–16 very severe electrical, wind, and rain storms prevailed over the northern district of Illinois. An observer in Henry County, Mr. W. W. Warner, noticed that for forty-eight hours before the storm not a sound was heard from the numerous song birds in the district. This observation was so full of interest that Mr. Linney wrote for additional information, with the result that he received numerous letters, some confirming it; others stating that birds sing louder and more persistently before a great storm, and nearly all agreeing that they are more restless than usual at such a time. Mr. Linney has found the following weather proverbs referring to song birds and storms:—When birds cease to sing, rain and thunder will probably occur.—If birds in general pick their feathers, wash themselves, and fly to their nests, expect rain.—Parrots and canaries dress their feathers and are wakeful the evening before a storm.—If the peacock cries when he goes to roost, and, indeed, much at any time, it is a sign of rain.—Long and loud singing of robins in the morning denotes rain.—Robins will perch on the topmost branches of trees, and whistle when a storm is approaching.—The restlessness of domestic animals and barn-yard fowls before an approaching storm is well known, and many of their peculiarities have been noted; but the actions of song birds do not appear to have previously received particular attention.

A FULL and well illustrated account of the manufacture of aluminium at Foyers is contained in *Commerce* for December 14. The works, which were completed at the end of 1896, are now in full operation. The raw material bauxite is obtained in County Antrim, whence it is transported to Larne. At Larne

it is calcined, ground, and treated under pressure with caustic soda solution, whereby sodium aluminate is formed. The clear solution of aluminate is then agitated, and at the end of thirty-six hours deposits 70 per cent. of its burden of alumina. This alumina is dehydrated and heated until it becomes crystalline and non-hygroscopic. In this state it is shipped to Foyers, where it is electrolysed in a bath of cryolite. The total fall of water available at Foyers is 350 feet, and an ample supply at all seasons has been secured by the conversion of two lochs into a reservoir of 4000 million gallons storage capacity—a large engineering enterprise. Seven turbines are at present in action, each capable of developing 700 h.p. when running at 140 revolutions per minute. The dynamos are of large size, the commutators being six feet in diameter, and having 216 segments. Each dynamo has 120 brushes. The carbon electrodes are made by the company at a factory in Greenock. The aluminium turned out at Foyers is not pure enough for all purposes. The refining works are at Milton, in Staffordshire, where plant is provided for an output of four tons daily. Aluminium now at 1*s.* 3*d.* per lb. is bulk for bulk cheaper than copper, brass or tin. The works at Foyers have called into existence a small village, which appears to be well looked after by the directors of the company. It already boasts a club, which provides recreation and instruction for the workmen.

LETTERS have lately appeared in the *Lancet* with reference to the colours of newly-born negro children. Several medical men have given the result of their experience, and the evidence shows that at birth the children are of the colour of a light quadroon. In a paper on the natives of the Warri district of the Niger Coast Protectorate, published in the new *Journal* of the Anthropological Institute, it is recorded that "pure negroes when born are pink, like young rats; at the end of about three or four months they become black." Atmospheric conditions thus seem to be necessary to produce the full black colour of the negro.

THE Anthropological Institute has just published the first number of a new series of its *Journal*. Since the foundation of the Institute an illustrated journal has been issued in quarterly numbers, forming, during the twenty-seven years of its existence, a series of as many volumes, containing numerous papers of great scientific value and interest. The old journal was a demy octavo ($5\frac{1}{2} \times 8\frac{1}{2}$ inches), but the new series is larger, being imperial octavo ($11 \times 7\frac{1}{2}$ inches, nearly). The object of increasing the size is to include ample plates and tables, and bring the journal in general uniformity with the important publications of some of the continental anthropological societies. A number of very interesting papers appear in the first part of the new series, among the subjects dealt with being the ethnography of the Murray Islands, Torres Straits, Australian folk-lore stories, the pigmies of the Upper Welle district of the Belgian Congo, A-bantu and Ashanti skulls and crania, the natives of Tanna, and totemism.

AN interesting paper by Dr. Brinton, on "The Linguistic Cartography of the Chaco Region," has just been reprinted from the *Proceedings* of the American Philosophical Society. The region known as El Gran Chaco, or the Great Hunting Ground, with which the paper is concerned, has always been peculiarly perplexing to students of American aboriginal languages. It lies in northern Argentina and eastern Bolivia, between latitude 18 and 32° South, and longitude 58° and 66 West of Greenwich. Except by the water-ways it is almost impossible to traverse the country, and for that reason extensive tracts of it are still unexplored. Dr. Brinton states that the native tribes who inhabited this region have always been in the lowest stages of culture, depending on hunting and fishing for their subsistence, without settled abodes, migratory and in ceaseless warfare with each other. The self-sacrificing efforts of the Jesuit and Franciscan missionaries have at times succeeded in gathering a few hundred together about some mission, only to be dispersed again on some slight cause. Thus, some years ago, in the middle of the night, the whole of the tribe of Penoquiquias, which had been converted and induced to take up a fixed abode, suddenly disappeared, and were never seen again. Dr. Brinton discusses recent contributions to the linguistic ethnography o the Chaco region, and offers some suggestions for the correct classification of tribes of still uncertain affinities.

ON September 20 and 21, 1897, two strong earthquakes were felt in the island of Labuan, near Borneo, the pulsations of which were registered by magnetographs at Batavia, Bombay and Potsdam, and by various pendulums at Nicolaiew, Catania, Ischia, Rome, Edinburgh and the Isle of Wight. The detailed records are given by Dr. Agamennone in the *Bollettino* (vol. iv. No. 4) of the Italian Seismological Society, and the same writer has investigated the velocity of the earth-waves in a paper read before the R. Accademia dei Lincei (*Rend.*, vol. vii. pp. 155–162). If the initial times be calculated from that given by the Batavia magnetograms, the velocities for both earthquakes would be 28 or 29 km. per sec., but there can be little doubt that the earlier vibrations are not shown on these curves, and that these estimates are consequently too great. Assuming, however, as is probable, that the magnetographs were not disturbed until the arrival of the long-period pulsations, Dr. Agamennone concludes that the first pulsations travelled with a velocity of $4\frac{1}{2}$–$6\frac{1}{2}$ km. per sec., and those which constituted the maximum phase with a velocity of $2\frac{1}{2}$–3 km. per sec.

THE Zoological Society have just issued the thirty-fourth volume of the *Zoological Record*, which contains a full account of the zoological literature of 1897, arranged in eighteen sections according to the usual plan of the work. The general editor of this most helpful publication is Dr. David Sharp, F.R.S. The various subjects have been undertaken by Mr. J. A. Thomson, Mr. R. Lydekker, F.R.S., Dr. R. Bowdler Sharpe, Mr. G. A. Boulenger, F.R.S., Mr. E. R. Sykes, Mr. E. A. Smith, Mr. G. C. Crick, Miss Florence Buchanan, Mr. A. W. Brown, Mr. F. A. Bather, and Dr. R. von Lendenfeld; while the general editor himself assumes the labour of the section relating to the Insecta, which occupies no less than 300 pages. The volume is prefaced by an alphabetical list of the abbreviations of the titles of publications used in the *Record*, which thus becomes a list of all the journals, *Transactions*, and other periodicals issued at the present time in which zoological papers are published. The number of these periodicals may be judged from the fact that the list contains 52 closely-printed pages. In this list the principal English libraries which contain copies of these periodicals are mentioned after every title. The volume concludes with an index to the names of new genera and subgenera proposed in 1897 and recorded in it, altogether 1574 in number. The corresponding total last year was 1541. No more useful piece of work could be done by the Zoological Society of London to facilitate the labours of working zoologists, and it is much to be regretted that all branches of science have not similar publications to assist the scientific "working man."

SEVERAL interesting papers on natural history topics appear in the *Transactions* of the Edinburgh Field Naturalists' and Microscopical Society (vol. iii. Part vii., 1898). Miss Sprague describes some common objects for microscopic study; Mr. W. Blacklock also deals with microscopy and some of its uses. The Rev. J. H. Lawrie gives an account of coral and coral-islands, with special reference to the New Hebrides group; and Mr. A. Murray contributes some interesting notes on the

life-history and habits of wasps. His paper contains an account of observations made by him of wasps in their natural state, extending over a number of years, and it thus possesses the merit of original work. In the course of the paper Mr. Murray remarks : " There is one thing which puzzles me much, namely, how a blackbird can stand at the side of a hanging wasps' nest, and tear it to pieces to devour the larva, and yet not be stung to death. The bird does not seem to be annoyed in any way, but if I venture to see what is going on, I am certain to be very much stung—I suppose, for not minding my own business." Among the other papers in the *Transactions* is one by Messrs. T. Scott and J. Lindsay, in which further results of the investigation of the micro-flora and micro-fauna of the Upper Elf Loch, Braids, are given. The paper illustrates the scientific benefits to be derived from a continuous examination of a particular loch or pond.

AT the Whitechapel Free Public Library and Museum, the following free science lectures (with lantern illustrations) have been arranged :—January 10, " How we digest our dinner," by Dr. E. H. Starling ; February 7, " A piece of limestone," by Mr. F. A. Bather ; March 7, " How animals warn their enemies and signal to their friends," by Cora B. Sanders.

WE have received the Christmas numbers of the *Gardeners' Magazine* and *Amateur Gardening*, both with very beautiful coloured illustrations, and a marvel of cheapness. Each periodical is also illustrated with photographs taken in well-known gardens at home and abroad, drawings of fruits and flowers, and others that will commend themselves to the gardener and horticulturist.

THE works from the library of the late Prof. Mariano de la Paz Graells are offered for sale by Herr Felix L. Dames, Berlin. A catalogue (No. 44) containing a list of works on natural history and zoology, vertebrates, anthropology, travels, and rare Spanish books on the chase and falconry, has just been issued. Lists of papers, &c., on invertebrates, botany, and entomology will be given in future catalogues.

IT will interest microscopists to know that Mr. Charles Baker, maker of optical and surgical instruments and accessories, proposes to commence a new department for lending microscopic specimens, much on the same lines as a lending library. The arrangement should be of service to many amateur microscopists, especially beginners and those living in districts where there are no microscopical clubs or societies.

THE *Agricultural Gazette of New South Wales* for September is largely occupied with an account of the different species or varieties of *Opuntia*, or prickly pear, that have been introduced into the Colony, and the various modes of exterminating them. So great a pest to the farmers has this plant become, that the Colonial Legislature passed, in 1896, a stringent Act imposing heavy penalties on the growth of it, or on failure to extirpate it on cultivated land.

MR. W. J. C. MILLER, who was for many years registrar of the General Medical Council, and had to resign his duties owing to a sudden breakdown, is, we are informed, now in a satisfactory state of health. In announcing his forthcoming work on "Nature Studies" (p. 155), he was referred to as the late Mr. Miller, and we are glad to be able to correct the wrong impression thus conveyed.

A BUNDLE of papers upon the methods and results of teaching speech and the knowledge of language to deaf-mutes has been received from the Volta Bureau, Washington, D.C. It may be remembered that this Bureau was founded in the year 1880 by Dr. Alexander Graham Bell, with the Volta prize of fifty thousand francs received by him for the invention of the telephone. It has for its objects the increase and diffusion of knowledge relating to the deaf, and performs most useful work in furtherance of them. The publications issued by the Bureau show that astonishing results are obtained by systematic instruction on sound principles.

THE *Journal of the Royal Microscopical Society* for December contains a continuation of Mr. Millett's report on the recent Foraminifera of the Malay Archipelago collected by Mr. Durrand, as well as the usual summary of recent researches in zoology, botany, and microscopy. In the latter department the President, Mr. Nelson, gives an interesting account of a binocular microscope designed and made by an amateur, and of an old microscope made by Mr. J. Cuff about the year 1760. This number also contains the very useful list of new terms in zoology and botany introduced during the year into scientific terminology.

FOR the purpose of understanding the effects produced on cultivation and hygiene by the variations of the weather and the changes in the composition of the atmospheric air, the Montsouris Observatory was charged to carry on experiments and investigate problems connected with the climate and hygiene of Paris. The work of the observatory is divided into three sections, which may be roughly described under the headings : physics and meteorology, chemistry, and micrography. Every year the observatory issues a small volume, "Annuaire de l'Observatoire Municipal de Paris," in which is embodied much valuable information based upon the researches and observations carried on under its direction. Containing, as it does, a mine of facts which should prove very useful to scientific workers, the volume for 1899, which includes an account of the work accomplished in 1897, will be welcomed by many.

THE *British Journal Photographic Almanac* has steadily increased in size for the past few years, and the new number for 1899 contains no less than 1508 pages ; this, of course, includes the host of advertisements, which by themselves are of interest to the photographer. Many of our readers are probably familiar with this annual publication, and will therefore know how difficult it is to make selections from the large amount of useful information given in it. We may say, with the editor, that the principal features of last year's volume have been repeated, and that all tables, formulæ, and other necessary facts for the photographer have been inserted and brought up to date. The volume contains, as usual, several specimens of reproduction processes, and illustrations of rapid shutter work, but they do not seem to be so numerous as in the previous publications. The Almanac should, however, be found in every studio, for the numerous facts contained in it will frequently be found of service.

THE compact little annual of the *Bureau des Longitudes* for 1899, published yearly by the National Convention to " propre à régler ceux de toute la Republique," is as interesting and complete as ever. It is unnecessary to refer to the detailed contents of the volume, but a statement of the alterations and additions that have been made in the present issue should be of interest. In the astronomical section the list of minor planets is brought up to September 13, 1898, and many details of these bodies, such as name, discoverer, date of discovery, duration of sidereal revolution, mean distance from sun, eccentricity and inclination are given. The table showing the elements of periodic comets has been revised, and a brief history is given of the comets which appeared in 1897. In the section devoted to geography and statistics, new values for the area of France, obtained from the Army Geographical Service, are inserted. M. Cornu has revised his article on electricity, and added a valuable note on electrical units as used in practice. The

articles included in the volume always give special interest to it; they are this year on the following subjects:—On sounding balloons, by M. Bouquet de la Grye; modern French geodesy by M. Bassot; on the large siderostat and telescope of 60 metres focal length and 1·25 metres aperture, which is being constructed by M. Gautier; and, lastly, on the work done at the Mont Blanc Observatory in 1898, by M. Janssen.

THE additions to the Zoological Society's Gardens during the past week include a Puma (*Felis concolor*) from Argentina, presented by Mr. T. S. Nicholson; a Red and Blue Macaw (*Ara macao*) from Central America, presented by Mr. H. Sneggitt; a Gannet (*Sula bassana*), European, presented by Mr. A. Trevor-Battye; a Greek Partridge (*Caccabis saxatilis*) from Greece, presented by Lieut. J. H. Mackenzie, R.N.R.; a Lapland Bunting (*Calcarius lapponica*), a Reed Bunting (*Emberiza schnoeiclus*) European, presented by Mr. F. Chatwin; two Black-winged Peafowl (*Pavo nigripennis*, ♂ ♀) from Cochin China, presented by Mrs. Johnes; a Hallowell's Tree Snake (*Dendraspis viridis*) from the Gold Coast, presented by Mr. J. W. Kaye; an Antillean Boa (*Boa diviniloque*) from the West Indies, three Horsfield's Tortoises (*Testudo horsfieldi*) from Central Asia, deposited; a Triton Cockatoo (*Cacatua triton*) from New Guinea; six Gadwalls (*Chaulelasmus streperus*) from Holland, purchased; three Rosy-faced Love-birds (*Agapornis roseicollis*), bred in the Gardens; an Urial (Wild Sheep (*Ovis vignei*, ♂) from Persia, received in exchange.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JANUARY 1899:—

January 2. Meteoric shower from Quadrans (Radiant 230° + 52°.)
2. 7h. 14m. Minimum of Algol (β Persei).
4. 15h. 38m. to 17h. 24m. Transit of Jupiter's Satellite III.
5. 10h. Venus at her greatest apparent brilliancy and a fine object in the morning sky. She rises about 3½ hours before the sun, and is situated 10 north of the red star Antares in Scorpio.
7. 17h. 3m. to 17h. 48m. The star 42 Libræ (mag. 5·2) occulted by the moon.
9. 19h. Mercury in conjunction with the moon (☿ 2° 56′ N.)
9. 10h. 38m. Partial eclipse of the sun visible at Greenwich.
11 14h. Mercury at his greatest elongation (23° 35′ W.), rising about 1¾ hour before the sun, and situated 10° east of Saturn, and 19° east of Venus.
11. 19h. 48m. Ingress of Jupiter's Satellite III.
15. Jupiter. Polar diameter 32″·8.
15. Venus. Diameter 35″·4. Illuminated portion of disc 0·332.
18. 12h. Mars in opposition to the sun.
18. Mars. Apparent diameter 14″·4.
19. 8h. 5m. to 9h. 14m. The star μ Arietis (mag. 5·8) occulted by the moon.
22. 15h. 33m. to 16h. 29m. The star 121 Tauri (mag. 5·4) occulted by the moon.
24. 17h. 32m. to 18h. 26m. The star 56 Geminorum (mag. 5·0) occulted by the moon.
25. 5h. 45m. Minimum of Algol (β Persei).
30. 13h. 39m. to 14h. 57m. The star B.A.C. 4006 (mag. 5·7) occulted by the moon.

It may be mentioned as a very unusual circumstance, that during the first half of January all the major planets of the solar system may be observed in the morning sky.

COMET CHASE.—The following is the ephemeris for comet Chase for the ensuing week. The comet is moving in the southern extremity of the constellation of Ursa Major, and lies a few degrees south of the star ξ Ursæ Majoris.

Berlin Mean Midnight.

ARTIFICIAL PRODUCTION OF SUN-SPOTS.—In the *Archives des Sciences physiques et naturelles* (November) M. Th. Lullin describes some experiments he has been undertaking with regard to producing the forms of sun-spots artificially. Commencing with the now generally assumed hypothesis that sun-spots are caused by the downfall of cool matter from the higher regions of the solar atmosphere to the lower and more intensely heated gases, he has been investigating the behaviour of splashes of water on a viscous substance, such as barium sulphate placed on a glass plate. An examination of the illustrations which accompany his paper, shows that, even with these crude imitations of the real elements at work, very striking results can be obtained which have their counterparts in actual sun-spots. Thus the striated appearance radiating from the umbra is well obtained, while the appearance of bridges can be easily reproduced. In these experiments there seems every hope that by imitating the results of the falls of separate streams or series of drops simultaneously on to a surface of some liquid of less density, still greater approximation to the actual appearances of solar spots would be obtained.

THE HEAVENS AT A GLANCE.—For the last two years Mr. Mee has issued a small card which contained a large amount of useful information arranged in chronological order, showing the amateur at a glance the sequence of astronomical events of interest for the year. Unfortunately the information on this card was not clearly printed, but was simply a reproduction of the original handwriting of the compiler: on this account the card was not such a useful addition to an observatory as it might have been. The new issue for the year 1899 has, however, been altered in this respect, and it is well arranged and clearly printed. The constellations visible, the declination of the sun, the phases of the moon, those planets that are well placed for observation, are given for each month, together with the times of appearance of the most prominent meteor showers, maxima and minima of the principal variables, &c.

These are followed by notes on the sun, planets, eclipses, and others containing just that information that the amateur should find most useful: symbols and abbreviations have been used as little as possible. Equipped with this card, possessors of small telescopes have a useful and simple programme of the astronomical occurrences for the year 1899.

ARE MOLDAVITES OF CELESTIAL ORIGIN?—Herr Dr. Franz E. Suess, of Vienna, has had the opportunity of studying several hundreds of specimens of pieces of moldavite which had previously been found between "Trebitsch and Dukowan, near Mahrisch-Kroman." These moldavites, which have a bottle-green, glass appearance, and are inclined to be egg-shaped, were first discovered at the beginning of this century, and very much doubt has been cast on their origin. In the paper before us (*Kaiserliche Akad. d. Wiss in Wien*, November 17), Dr. Suess describes previous theories of origin suggested, and gives his own reasons for the opinion he has formed. A thorough examination of very many specimens has led him to believe that their surface forms can in no way be explained by weathering or collisions, but that these surface markings seem to be very closely related to the indentations of meteorites. All the surface markings on these moldavites can be explained on the assumption of the influence of an enormous air resistance. Dr. Suess then describes the differences in form of the surfaces he examined, and classifies them under different headings. In concluding his remarks, he suggests that the reason why the origin of these moldavites has not been previously attributed to the same as that of aerolites, can be accounted for only on the curious chemical nature of these bodies. Considering the comparative little knowledge we possess concerning the chemical nature of bodies of cosmical origin, we must conclude that we "must add to the known groups of aerolites a new group, namely moldavites."

It would be interesting to make a spectroscopic examination of some of these specimens, and compare their spectra with those of other meteorites that have been previously examined.

JUPITER AND HIS MARKINGS.

JUPITER is now coming into a favourable aspect in the morning hours. His position about ten degrees south of the equator will, however, be an unfortunate circumstance for European observers. To those, however, who can command an open southern sky, there will be plenty of opportunities for successful research; and, certainly, this magnificent planet deserves all the study that can be possibly devoted to him. In 1899 it is to be hoped that a great number of drawings will be made, and that the latitudes of the belts and spots will be micrometrically determined. We also require a fresh and extensive series of the times of transit of the principal light and dark markings, so that their longitudes and rate of drift relatively to the zero meridian may be ascertained. The latter element requires close attention at every opposition, as the velocities of the various currents are frequently changing, and it is possible they are regulated in definite cycles.

During the last opposition the planet received widespread notice from many observers, including Brenner, Fauth, Gledhill, Hough, MacEwen, Phillips, Comas Solá, Stanley Williams, myself and others. No very special phenomena were presented to arouse so much interest, but the disc was replete with a variety of interesting formations. The equatorial region exhibited an abundant series of dark and bright spots. These were moving more rapidly than similar and probably identical features last year, the difference of velocity being about 10 seconds. It will be important to determine whether a further acceleration of speed occurs in 1899. In 1897 the mean rotation of the equatorial current was 9h. 50m. 34·6s. according to Mr. Williams, while in 1898 the writer found it 9h. 50m. 23·6s.

In the north tropical zone there were several dark elongated spots visible during the last opposition. These completed a rotation in about $15\frac{1}{2}$ seconds less than the red spot. This latitude, about 15° N. of the equator, appears to be very prolific in the production of dark and light spots, which in certain cases remain visible over considerable intervals. During the past few years these markings have presented some difficulties as to their identification, for some of them appear to be subject to variations in form and tint, and perhaps to temporary obscuration. They also, during different oppositions, exhibit a variable rate of velocity. Thus in 1894-5 a very dark and definite spot was seen on the northern edge of the north temperate belt. In the next opposition two other spots, which were known as the "violin" and "garnet" spots, were displayed in the same latitude, though the north side of the belt seemed to have vanished. In 1897 no conspicuous spots were detected in this zone, but several were seen in 1898, and one of these may possibly have been identical with the chief spot of 1894, and with the violin spot of 1895-6, as the following comparison of longitudes and rotation periods, obtained at Bristol, will indicate:—

		Longitude. °	Rotation period. h. m. s.
Dark spot ...	1894 November 5 ..	239·1	9 55 37·8
	1895 May 9	226·3	
"Violin" spot	1895 September 26 ...	222·6	9 55 33·8
	1896 February 9 ...	201·1	
1896-7 Spot apparently invisible.			
Dark spot "A"	1898 March 23 ...	126·7	9 55 27·7
	July 4	94·7	

The decreasing longitude of the spot agrees fairly well, and the rapid increase of velocity is well marked along the series, but the evidence that the objects were identical is certainly not conclusive. If the spot was temporarily hidden in 1896-7, its rate was probably 9h. 55m. 30·7s. It is curious that in 1890 Prof. Barnard found the rate of a dark spot in same latitude 9h. 55m. 30·3s.; while in 1891 Prof. Hough derived a value of 9h. 55m. 27·4s. from a mean of two spots. From a comparison of a large number of rotation periods of this current at different times, it appears a probable inference that the time oscillates between 9h. 55m. 26s. and 9h. 55m. 41s. in a period of about seven years. This is somewhat doubtful, but the variation of rate seems well marked and to give evidence of regular periodicity. It will be especially interesting to redetermine the rotation period during 1899 if spots are still displayed in this latitude.

With reference to the red spot, I re-observed it on November 29 at 19h. 55m., when it was on the central meridian, and followed the zero meridian of System II. by about fifty-three minutes.

The question has often been asked as to whether the great red spot of modern times is identical with Cassini's spot of 1665 and following years? There seems a large amount of significant evidence to support the affirmative view. The observations spread over the 234 years, from Cassini's first observation to the present time, do not afford many connecting-links, but the probabilities are all on the side of identity.

Though the ancient object is generally called Cassini's spot, it was really discovered by Robert Hooke, with a telescope of twelve feet focus and two inches aperture, on 1664 May 9. He detected, "at about nine o'clock at night, a spot in the largest of the three obscure belts of Jupiter, and found that within two hours afterwards the said spot moved east to west about half the length of the diameter." To Hooke, therefore, belongs the credit of discovering this object, and the indication it afforded of fixing the exact time of rotation of the planet. But Cassini took the marking under his special charge, seeing, as he did, the important deductions to be made from it. Observing it frequently in the summer of 1665, he ascertained the rotation period as 9h. 56m. I have gone over many of Cassini's observations, and make the corrected period of rotation 9h. 55m. 47·5s. in 1665-1672. Cassini says he was assured of the preciseness of one mean revolution to one-eighth of a minute. On 1672 March 1, he saw the spot in transit on two occasions (viz. at 7.30 and 17.26), and announced to the French Academy of Sciences on the following day that the spot might be again seen in transit on March 3 at 9.8 p.m. The Academy thereupon deputed two of its more prominent members to verify Cassini's prediction. With this purpose in view, they repaired to the observatory, and, in company with Cassini, actually observed the spot return exactly as foretold by him.

The spot seen by Hooke and Cassini was about one-tenth of the apparent diameter of Jupiter; this would be about 9000 miles, and equivalent to the width of the spot in recent years. The oval shape it now presents may be due to the rapid rotatory motion of the sphere, which we know has the effect of spreading out objects in a longitudinal direction. Several new belts have been formed under the eyes of observers. But in the case of the red spot, its material may have been sufficiently solid to withstand the winding-out process beyond the elliptic form which became its permanent shape.

If the spot which Hooke saw on 1664 May 9, was the same as the relic of the red spot observed at Bristol on November 29 last, then in the interval of $85{,}670\frac{1}{2}$ days no less than 207,084 rotations have been performed, if we adopt the mean rate as 9h. 55m. 40s. during that long interval. It is quite possible to trace back the spot or its accompanying hollow in the great southern belt to 1831, and a further search amongst old drawings of Jupiter may take its history safely back to the time of Sir William Herschel and J. H. Schroeter. W. F. DENNING.

THE NEW LIVERPOOL MUSEUMS EXTENSION BUILDINGS.

THE present museums buildings were erected in 1860 by the late Sir W. Brown for the splendid natural history collections bequeathed to the City of Liverpool by the XIIIth Earl of Derby in 1851. These were so extensive that the accommodation they required necessitated the building of what was, at that time, one of the largest museums in England outside the Metropolis. Since that date the collections have been constantly added to, not so much by purchases, as by gifts—some of them of the highest value—from donors possessing an interest in natural science, and appreciating, in advance of their time, the importance of that subject as a means of education, with the result that, to-day, every available foot of space in the museums has long been occupied—every cellar even being stored to its utmost capacity—so that any intelligible arrangement of their contents has now become well-nigh impossible. Within the past decade, also, the change in the public attitude has been growing very rapidly towards an appreciation of museums as institutions of high educational value and importance. This is due, no doubt, to the rapid increase of scientific and technological knowledge, and to the advocacy of no one in Europe so specially as Sir William Flower, who, by his writings, and, perhaps, principally by the methods, inaugurated by him, of displaying and labelling the specimens in the Natural History Museum in South Kensington, has made manifest, not the

interest only, but the educational value of the study of natural objects. The Corporation of Liverpool has been one of the first to recognise this advance in opinion in raising the city's museum to the position of a first-class scientific institution, by voting the necessary funds for its proper support, and keeping the collections abreast of the stream of discovery.

The additions—chiefly by purchase—to both the Derby and Mayer Museums have been within the last three or four years so specially numerous that since 1893 it has been evident to the Museums Sub-Committee of the Libraries, Museums, and Art Committee of the Council that increased space was urgently necessary.

The Technical Instruction Sub-Committee then also found itself in the same position in regard to a central school to accommodate the more advanced classes, which were and are now being held in widely separated parts of the city, in buildings most of them ill adapted for teaching purposes.

A special Sub-Committee was therefore constituted in December 1894, empowered to take immediate steps for the extension of the museums, and for providing suitable accommodation for the Liverpool School of Science, Technology, and Art The credit of overcoming the difficulties which beset the initiation of so large a scheme, and of arranging the preliminaries, is chiefly due to Sir William Forwood.

The present museum buildings stand on a rocky plateau sloping abruptly towards the west. By excavating this slope, consisting of Permian rock, down to the level of Byrom Street, sufficient accommodation, three stories in height, could be provided for the Technical Schools, while the museum galleries could be carried forward, on their present level, over the schools. The Technical Schools will thus be distinct and entirely isolated, and have their own entrance in Byrom Street.

This being so, designs with estimates for a building—whose requirements were sketched out by the Director of Technical Instruction and the Director of Museums respectively—were invited from a selected list of architects of eminence in England. In the summer of 1896 the designs of Mr. Edward William Mountford, of London, were awarded the first premium. The handsome and stately building so designed, which is represented in the accompanying illustration, will be 90 feet above the level of Byrom Street, and measuring from north to south 162 feet, and from east to west 190 feet, occupying an area of 27,000 square feet. The galleries of the museum will run in continuity with those in the existing building, and will be undivided in any part of their course by walls or partitions. They will be of horse-shoe shape, and 420 feet in length, 33 feet in breadth; the lower—to contain the Invertebrates—19 feet in height, while the upper—for the Vertebrates—will be 27 feet. The lower floors will be lighted from the side, and the upper from the roof. New and well-appointed laboratories—which, when the first building was erected, had been entirely overlooked, or, at that date, considered quite unnecessary adjuncts to a museum—for the director and his assistants, are also to be provided, as well as new administrative offices.

The new buildings will be of brick, faced with Stancliffe stone from the quarries at Darley Dale, in Derbyshire, the same which furnished the material of which St. George's Hall is built. They will be the largest built by the Corporation of Liverpool for fifty years, and the largest since the erection of St. George's Hall, and, next to it, the largest building in the city. The front to Byrom Street rises from the very edge of the original "Pool," and is close to the site where the old bridge connected Liverpool with the heath.

The ventilation and heating of the buildings will be carried out on a system which provides upwards of four miles of three-inch pipes, discharging into every room purified and warmed air to the amount of 8,000,000 cubic feet per hour. The stairs are of stone, the floors of concrete, and the roof chiefly of steel, so as to reduce the chance of fire to a minimum; in case of which, however, an emergency staircase will provide exit for visitors in the museum.

The New Central Technical Schools and Museums Extension Buildings, Liverpool.

The work of excavating the rock, of which the slope extending west of the present museums is composed, was commenced on November 1, 1897.

On July 1 last the foundation stone was formally, and very appropriately, laid by Alderman Sir William Bower Forwood, who has for many years been Chairman of the Standing Committee in charge of the libraries, museums, and art gallery, and to whose energy and powerful advocacy, not only the approaching realisation of this much-needed extension of the two departments of technical instruction and the museums are, in a very special manner, due, but also the large increase and development of the two other departments under his chairmanship—the libraries and the art gallery.

On the stone being "well and truly laid," Sir William Forwood gave an interesting address, in which he said the City Council, by that day's proceedings, announced to Liverpool that they believed that technical instruction had come to stay with them; that it was now part of the life of the people; and that it was worthy of that magnificent home. This building

would complete what he believed would be the most unique group of buildings in the world. It was intended for the higher technical education—for educating the captains of labour, and not merely the artisans, in a way that would enable them to meet the competition of Germany. The Germans had had these superior schools for years, and had been turning out a large number of expert and scientific men such as did not exist in England. They, however, hoped to make them exist in Liverpool, and he also hoped that this building would enable them to start in Liverpool many new industries that would give employment to the surplus population, and especially to females.

Speaking of the accommodation which would be afforded to the museum, Sir William reminded them that it had been founded by a bequest by the XIIIth Earl of Derby, some sixty years ago, and had been strengthened year by year by purchase. They were able to display only about one-half of their collections, and even that was so crowded that it was impossible to attempt any classification. This building would enable them to unpack and arrange scientifically the whole of their treasures, and in a short time they would have a museum unequalled out of London. When visiting Rome, Florence, Venice, and Athens, they were attracted there, not by what the Cæsars and Doges had done, not by the spoils of war, but by the monuments of art and the stores of literature which were left behind in these cities. In the same way he hoped that these buildings would tell future generations that, while they had been strenuously engaged in commerce, they had not been forgetful of the intellectual welfare of the citizens, knowing that by doing so they were promoting public morality as well as the material prosperity of the people.

ECONOMIC BOTANY IN NYASALAND.

THE following interesting notes on some of the exotic economic trees and shrubs cultivated in the Residency Grounds, Zomba, British Central Africa, are given by Mr. John Mahon, Government Botanist, in the annual report on the Protectorate for the year 1897-98 (C-9048). Accompanying the notes in the report is a complete list of exotic trees and shrubs growing at Zomba.

The collection of exotic plants grown at Zomba possessing economic value is not at present very extensive, but it is being steadily added to. The Coffee-disease Regulations in force prevent plants or seeds being imported from several tropical centres where we could obtain many valuable things, and the long journey from England hinders us from obtaining plants in Wardian cases from the Kew establishment or any of the large nurseries, except the consignment is taken in hand by some officer of the Protectorate, or the like, who is making the voyage out and sees it safely through. The authorities at Kew, having such unusual opportunities for distributing seeds, frequently forward valuable material to us, and many of the items mentioned emanated from Kew, either as seeds or plants. The list forms an interesting record of the cultural possibilities in the climate of the Shiré Highlands. There are but few countries where one can see such an essentially cool and northern type of vegetation as the Lawson cypress (which bears seed in enormous quantities) growing alongside such an essentially tropical type as the gutta-percha of Malaya (*Dichopsis gutta*). Although it is true the latter does not reach its proper degree of development, yet it is perfectly healthy, and it points to the fact that in the lower and warmer region on the Shiré River it would be a valuable culture.

Many of the items mentioned are only represented by one plant, and many of them are not old enough to have reached the fruiting period. Some of the introductions grow with surprising vigour. For instance, eucalyptus, the seeds of which were sown about six years ago, are now over sixty feet high, and would yield very capable timber if required. The well-known blue gum is not, however, a success here, but it seldom is in these latitudes below the 5000 feet level. Still there remains numerous equally good, and even better, members of this useful genus which we can cultivate with success.

Mauritius hemp (*Furcræa gigantea*) and sisal hemp (*Agave rigida*, var. *sisalana*) grow with great freedom, and while it would scarcely pay to cultivate these valuable fibres at present for the European market, yet if any textile industries arise locally there can soon be plenty of raw material at hand to supply them.

Seeds of the celebrated China grass (*Boehmeria nivea*), a fibre very much in demand now, have been ordered, and it is intended to demonstrate that it is a profitable culture that might be grown in Nyasaland with the object of exportation to the European markets. Arnatto (*Bixa orellana*) fruits with great profusion; the seeds are used in the arts as a dye, and as colouring agent for butter; the supply at present, however, from Colonies like the West African, exceeds the demand.

Fruits are a very important culture in all tropical countries, and the indications point to the Shiré Highlands being suitable for raising the fruits of many diverse countries. The mango (*Mangifera indica*) grows with much luxuriance, but as all the existing plants at Zomba have been introduced recently they have not yet reached the fruiting stage. One tree is expected to yield some fruit this year. The same applies to oranges, avocado pear, and guavas, although at present one tree of the latter is maturing fruits. (On the Buchanan estate, close to the Residency, oranges bear with great profusion, and up till recently peaches were a great success there.) The granadilla (*Passiflora quadrangularis*) fruits freely, and the fig (*Ficus carica*) seems quite at home. The grape vine grows well, and is a recent introduction; we expect to see it fruiting next year. Bananas, it need hardly be remarked, bear with great abundance. Up to the present this is practically the only fruit the native grows.

Exotic timber trees are very promising. The red cedar (*Juniperus virginiana*) and West Indian cedar (*Cedrela odorata*) do extremely well, and are important in view of the expected development of the tobacco industry, as they supply material from which first-rate cigar boxes can be manufactured. Kauri pine (*Dammara Australis*), a timber of great value and utility, promises to become a great success here, for seedlings planted a year ago have reached over three feet in height. Mahogany does very well. The good offices of Kew have been requested in obtaining for us a large quantity of seeds in order that we can grow it on a considerable scale and distribute it over the Protectorate. The splendid Mlanje cedar (*Widdringtonia whytei*) grows with unexampled vigour at Zomba, which is at least 3000 feet lower than its native habitat. It is very interesting to find it doing so well here, and points to the fact that in time the hills of Nyasaland above the 3000 feet level can be successfully forested with this excellent timber. Seeds from the trees at Mlanje have been widely distributed amongst Government officers, missionaries, and planters in the Protectorate, as well as to various parts of Southern Africa.

Perhaps enough has been said to indicate the diversity of cultures possible in the Protectorate. The Botanical Department at Zomba is very young yet, but endeavours are being made to render it of service to the country. As it is, it can demonstrate that many plants of commercial importance find a suitable home in the soil and climate of Nyasaland.

THE IRON ORE DEPOSITS OF NORTHERN SWEDEN.

OF the excursions in connection with the last meeting of the Iron and Steel Institute in Sweden, none was of greater interest than the visit to the vast mountains of iron ore at Kiirunavaara and Luossavaara within the Arctic Circle. The party of members invited by the owners of the mines was necessarily limited, and the journey was long and arduous. After travelling 820 miles by railway, the party proceeded in carriages for forty miles over a loose shingle road, then for forty miles more up the Kalix river in boats poled against the stream, and lastly for ten miles on foot. The visit to the mines was made under the guidance of Mr. H. Lundbohm, of the Geological Survey of Sweden, who contributed to the meeting an interesting paper describing the deposits. From this the following details are derived:—

The character of the country is very remarkable. The Kiirunavaara mountain consists of a steep ridge extending for about 2½ miles, divided into a series of peaks varying in height from 270 to 2450 feet above the lake Luossajärvi, which separates it from the gently sloping conically shaped Luossavaara. On the tops of these mountains the ore lies almost entirely uncovered by soil; on the sides it is covered by morainic material and beds of gravel and sand; while the mountains are

surrounded by extensive morasses. The ore occurs in bed-like masses in porphyries of varying character and composition. The total length of the Kiirunavaara ore body is 15,500 feet. The width is usually 330 feet, but in one place it is as much as 840 feet. The dip varies from 45° to 60°. It is estimated that the quantity of ore available above the level of the lake at Kiirunavaara is 215,000,000 tons, and at Luossavaara 18,000,000 tons.

The Kiirunavaara ores differ widely from most Swedish ores. They are unusually hard and compact, and remarkably free from all foreign minerals except apatite. That mineral is, however, exceedingly abundant. Analyses show that ores occur with less than 0·05 per cent. and from 0·05 to 0·1 per cent. of phosphorus in such quantities that they can be mined separately. The bulk of the ore, however, contains 1 to 4 per cent. of phosphorus. The percentage of sulphur is usually 0·05, and sometimes less than 0·02. Titanium varies from 0·32 to 0·95 per cent., and manganese does not exceed 0·32 per cent. The great bulk of the Luossavaara ore is comparatively low in phosphorus, and much of it appears to be well adapted for the acid Bessemer process.

No serious attempt was made to work these deposits before 1880, when a concession was granted for the construction of a railway from Luleå to the Ofoten fjord; but the concession was withdrawn after the railway had been completed from Luleå to the iron mines at Gellivare. This year, however, the Swedish parliament authorised the construction of a railway from Gellivare, past the Kiirunavaara and Luossavaara deposits, to the Norwegian frontier; and the Norwegian parliament has authorised its being continued to Victoria Harbour, on the Ofoten fjord, a port free from ice throughout the year. The distances from the iron ore deposits along the projected line of railway are—to Gellivare, 63 miles; to Luleå, 182 miles; to the Norwegian frontier, 79 miles; and to Victoria Harbour, 120 miles. Within a short period these vast supplies of iron ore will thus be rendered available, and British ironmasters will have within easy reach sufficient ore to last for many generations to come.

ELECTRICAL STAGE APPLIANCES.

THE proposed application of electrical power for mounting plays at Drury Lane, on the lines advocated by Mr. Edwin O. Sachs, has now taken a tangible form in the completion of the first section of the stage installation in time for the impending pantomime.

Mr. Sach's present work refers principally to the stage floor and its movability in sections above and below the footlights. The total area now already movable by mechanical power exceeds 1200 square feet.

The electrical appliances just completed take the form of so-called "bridges," each working independently. Each individual section measures 40 feet by 7 feet, and weighs about 6 tons, of which about 4 tons are counterbalanced. They can travel about 20 feet vertically.

The motive power is from the ordinary electric supply mains over a four-pole motor, developing 7½ horse-power at 520 revolutions per minute. The "bridges" are suspended from cables, and these, working over the motor, allow the former to be raised with the necessary live load at rates varying from 6 feet to 20 feet per minute.

Every possible safeguard has been taken against accident, the "bridges" themselves being so constructed that in the event of derangement of current the appliances can be worked by hand gear. Automatic switches are provided so as not to be entirely dependent on the attendants, and automatic catches will work in case of rope-breaking. Special locking-gear has been installed to hold the "bridges" stationary at certain points, such as stage level, and a very large factor of safety has been allowed in apportioning the strengths and weights in the various parts of the mechanism, having special regard to the ever-increasing scenic requirements under Mr. Arthur Collins's able management.

As regards the economic aspect of the electrical installation, the initial outlay on the system adopted is about half that of continental hydraulic work. The maintenance is minimal, whilst the actual working only costs a few pence per performance. The saving in manual labour on the stage is very considerable, whilst the hygiene of the theatre is materially raised by the absence of woodwork.

METALLIC ALLOYS AND THE THEORY OF SOLUTION.[1]

THE term alloy in its technical sense is used to indicate a solid mixture of two or more metals. The earlier investigators in this field, such as Matthiesen, Richie and many others, worked mainly with solid alloys, and they endeavoured to investigate the change in properties of the alloy, such as conductivity for heat and electricity, malleability, ductility and the like, with successive small changes in composition.

This method, although well adapted to bring out properties of alloys suitable for use in the arts, has not till recently shed much light on the real constitution of this interesting group of substances. Chemists have neglected the subject because the ordinary processes by which they attack problems fail them when dealing with alloys, on account of their opacity, want of volatility and power of being separated from one another by crystallisation. Another difficulty arises from the fact that the resulting alloy has usually the same colour as the metals from which it is produced, except in a few cases, such as the rich purple alloy of gold and aluminium investigated by Prof. Roberts-Austen, and the alloy of zinc and silver noticed by Matthiesen and investigated by Neville and Heycock, which has the property of taking a superficial rose tint when heated and suddenly cooled.

During the past twelve years considerable advance has been made in the study of alloys by investigating some of their properties whilst in the liquid state, such as the temperature at which solidification commences; it is convenient to term this temperature the freezing point. Le Chatelier, Roberts-Austen, Neville, myself and others have all worked in this way. The result of this work may be very briefly stated as follows.

Solutions of metals in one another obey the same laws that regulate the behaviour of solutions of such substances as sugar in water. For example, if we take solutions of sugar of different concentrations, but not exceeding 3 or 4 per cent., we find that within these limits the lowering of the freezing point is nearly proportional to the concentration. Exactly in the same way, if we add to a quantity of molten sodium (freezing point 97° C.) some gold, we find the gold dissolves much in the same way that sugar dissolves in water. On determining the freezing point of the alloy we find that it is lowered in direct proportion to the weight of gold added, notwithstanding the fact that pure gold by itself melts at a temperature of 1060° C. It is remarkable that the effect of increasing the quantity of gold in the alloy continues to depress the freezing point of the sodium, until the alloy contains more than 20 per cent. of gold when the minimum freezing temperature 81·9° C. (eutect temperature) is reached. The case of gold dissolving in sodium may be taken as a very general one, for a large number of pairs of metals have been examined, and with but few exceptions, such as antimony dissolved in bismuth, the effect is almost always to produce a lowering of the freezing point of the solvent metal. By the solvent metal we generally mean the metal which is present in the largest quantity.

A second point in which metallic alloys resemble ordinary solutions is in the fact that the depression of the freezing point is inversely proportional to the molecular weight of the dissolved substance. Thus, if we dissolve 342 grams (molecular weight in grams) of cane sugar in 10 litres of water, and determine the freezing point of the solution, it is found to be depressed a definite number of degrees below that of pure water. But the same depression of the freezing point is produced by the solution of 126 grams of crystallised oxalic acid, or only 32 grams of formic acid, in 10 litres of water.[2] Alloys again appear to obey the same law; thus it is found that if we dissolve 197 grams of gold, or 112 grams of cadmium, or 39 grams of potassium, respectively, in a constant weight of sodium, the freezing point of the sodium will be lowered by almost the same number of degrees in each case. Now the numbers 197, 112 and 39 are the atomic weights of the metals, and it can be shown that these numbers are also probably the molecular weights of these elements. Hence we conclude that metals dissolved in each other obey the same laws as ordinary solutions.

The above facts for the behaviour of solutions of substances

[1] A discourse delivered at the Royal Institution by Mr. Charles T. Heycock, F.R.S.

[2] Although water is used as a solvent by way of illustration in these cases, it should be stated that it is by no means a suitable liquid for such experiments, owing to the changes it brings about in the substances dissolved. In making such experiments it is far preferable to use benzene or acetic acid as a solvent.

in water and organic liquids have been gradually accumulated by the work of Blagden, Rüdorff, Coppet and Raoult, extending from about 1780 to the present time, but no general explanation of them was brought forward until Van 't Hoff advanced the remarkable theory that a dissolved substance was in a condition somewhat analogous to that of a gas, the solvent substance serving the part of the vessel in which the gas is confined, but also exerting other effects.

He further gave strong reasons for believing that substances in dilute solution obeyed the same laws that gases do—*i.e.* the laws of Boyle and Charles for temperature and pressure. Several other theories of solution, besides what may be termed the gaseous theory, have been proposed. Notwithstanding that some weighty objections can be urged against this theory, it is remarkable that we can by aid of it predict the numerical values for the fall of the freezing point of different solvents produced by the solution of other substances, provided that we know the latent heat of fusion of the solvent.

On applying the same reasoning to alloys, we find that the theory holds good, as the table below shows.[1] We see from

Observed Depression in the Freezing Point of a Solvent Metal, caused by the Addition of One Atomic per cent. of a Second Metal.

Solvent		Tin	Bismuth	Cadmium	Lead	Zinc
Depression calculated on theory of Van 't Hoff		3·0° C.	2·08° C.	4·5° C.	6·5° C.	5·11° C.
Metal dissolved	At. Wt					
Sodium ...	23	2·8	2·0	4·5	1·2	—
Copper ...	63	2·9	1·2	3·6	6·3	1 5 (rise)
Silver ...	108	2·9	2·0	10·8 (rise)	6·6	5·15 (rise)
Platinum ...	195	—	2·1	4·5	6·4	—
Gold ...	197	2·9	2·1	1·6	6·4	3·4 (rise)
Bismuth ...	209	2·4	—	4·5	3·0	5·1

this table that in no cases are the observed depressions of the freezing points greater than those calculated from the theory, but in many cases they fall below this quantity; this latter fact admits of explanation.

On the theory of Van 't Hoff it is necessary that when a solution begins to freeze the pure solvent should separate out first. This admits, in case of aqueous solutions, of simple proof; for if we take a dilute solution of potassium of permanganate and make it freeze slowly, we find that pure colourless ice separates out on the walls of the vessel, whilst the purple permanganate is concentrated towards the centre. This experiment led Neville and myself to try if a similar state of things could be shown for metallic alloys.

We have great pleasure in bringing before the Royal Institution this evening the first announcement of the results we have obtained. For this purpose we took two metals, gold and sodium, the former being very opaque to X-rays, whilst the latter is very transparent to them. A quantity of sodium was melted in a tube, and gold dissolved in it to the extent of about ten per cent. The alloy was then allowed to cool extremely slowly, and sections (about ⅛ inch thick) were cut from different parts of the solid alloy and placed between thin plates of aluminium to protect them from the air. These sections were then placed on a photographic plate, enclosed in a light tight bag, and exposed to the action of the X-rays. On developing the plate we found a complete picture of the inside of the alloy. Positives obtained from these negatives are thrown upon the screen. The sodium is seen to have crystallised out in plates, as is evident from its transparency, whilst the opaque gold is seen to have become concentrated in the mother liquor between these plates, where it finally solidified along with some of the sodium.

Very similar results are produced with other pairs of metals, such as aluminium and gold and aluminium and copper. Behrens, Roberts-Austen, Osmond and others have examined alloys, after superficial etching, with high microscopic powers, and they find a similar separation of the constituents.

We thus see that solution of metals in one another follows extremely closely the same laws that regulate solutions with which we are ordinarily familiar. I should like to state here that the matter of this lecture is largely drawn from the work carried out by Mr. Neville, F.R.S., and myself during the past six years.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The electors to the Linacre Professorship of Comparative Anatomy will proceed to an election in the course of Hilary Term, and candidates are desired to send in their names to the Registrar of the University not later than January 31, 1899. The Board of Electors consists of the Visitor of Merton College (the Archbishop of Canterbury), the Presidents of the College of Physicians and the College of Surgeons, the Waynflete Professor of Physiology, the Regius Professor of Medicine, an elector appointed to represent Merton College, and an elector appointed to represent the Hebdomadal Council. The Hon. G. C. Brodrick, Warden of Merton, has been appointed by Merton College, and the Dean of Christchurch by the Hebdomadal Council.

The electors to the Sedleian Professorship of Natural Philosophy, vacant by the resignation of Prof. Price, will also proceed to an election in the course of Hilary Term, and names of candidates are to be sent in not later than January 31. The Board of Electors consists of the Vice-Chancellor, the President of the Royal Society, the Provost of Queen's College, the Professor of Experimental Philosophy, Savilian Professor of Geometry, an elector appointed to represent Queen's College, and an elector appointed to represent the Hebdomadal Council. Prof. Elliot and Prof. Rücker have been chosen as the last-mentioned electors.

THE Calendar of University College, London, for the session 1898–99, has just been received. The purpose of the College, as expressed in the Act of 1869, whereby the College was re-incorporated with additional powers, and divested of its proprietary character, is "to afford at a moderate expense the means of education in literature, science, and the fine arts, and in the knowledge required for admission to the medical and legal professions, and in particular for so affording the means of obtaining the education required for the purpose of taking the degrees now or hereafter granted by the University of London." During last session the following new departments were created: Laboratory of Experimental Psychology, Pender Chair of Electrical Engineering, the Edwin Chadwick Chair of Municipal Engineering. It is interesting to note that in the department of applied mathematics, Prof. Pearson gives, in the place of advanced class examinations, subjects for dissertations referring to the mathematical theory of statistics.

MR. W. C. MCDONALD's benefactions to the McGill University, Montreal, have often been the subjects of notes in these columns, and last week we recorded that he had received the honour of a knighthood in recognition of his gifts to philanthropical and educational objects in Canada. Mr. McDonald's princely gifts to the McGill University include 20,000 dollars to the Workman endowment for mechanical engineering; the erection of the W. C. McDonald engineering building, valued, with its equipment, at 350,000 dollars, and an endowment for its maintenance; the endowment of the chair of electrical engineering with the sum of 40,000 dollars; the erection and endowment of the physics building, valued at 300,000 dollars, and two chairs of physics with endowments amounting to 90,000 dollars; the endowment of the faculty of law with 150,000 dollars; the endowment and equipment of the chair of architecture; a further sum of 150,000 dollars for the maintenance of the engineering building; 50,000 dollars towards the endowment of the pension fund; and the erection of a new building for the Department of Chemistry, Mining, and Agriculture, at a cost of 500,000 dollars, making the total amount contributed to the institution upwards of 1,600,000 dollars.

THE Executive Committee of the Central Welsh Board have unanimously passed the following resolutions, among others, referring to the Board of Education Bill, and have forwarded copies to the Education Department and the Charity Commission, with an intimation that they will be brought before the

Central Board at their half-yearly meeting in April next. "That Clause 1 (2) of the Bill should be amended by omitting the words 'one other person,' in order to insert the words 'two other persons, one of whom shall be a person well acquainted with the conditions of Wales and the wants of the people.'" "That considerable difficulty might arise in the future from the apparently concurrent jurisdiction of the Board of Education and the Charity Commission foreshadowed in Clause 2 (2) and (3), and that it is important therefore that the Bill should be so amended as to provide for a completer fusion of these two bodies." "That the Bill should be so amended as to indicate clearly that there will be no interference with the present organisation of intermediate and technical education in Wales and Monmouthshire under the Welsh Act, and that provision should be made for preserving to the Central Welsh Board the functions exercised by it under its scheme, and under the Treasury regulations already in force, for the inspection and examination of schools in the Principality." "That the Central Welsh Board might properly be regarded as a Consultative Committee, to which matters specially connected with Welsh education might be referred by the Board of Education for consideration and report."

SCIENTIFIC SERIALS.

American Journal of Science, December.—Another episode in the history of Niagara Falls, by J. W. Spencer. The first episode of the river was characterised by a cascade comparable in size to the American Falls, draining the Erie basin alone. The commencement of the second episode was marked by an increase in the volume of water, owing to the drainage of all the upper lakes being turned into the Niagara. Subsequently the fall was increased from 200 to 420 feet. Instead of continuing until reduced to its present height of 326 feet, the author now believes that it was reduced to a lower amount, 250 feet, and subsequently increased. This additional episode accounts more fully for the narrows of the gauge than any previous explanation. The age of the Falls will probably come out a little different from 32,000 years, but their fate will be the same. They will disappear by the lakes being drained into the Mississippi basin by way of Chicago.—An apparatus for measuring very high pressures, by A. de Forest Palmer, jun. The pressure in a Bessemer steel cylinder filled with heavy oil compressed by a tinned-steel screw is measured by a thread of mercury in a capillary tube whose resistance alters with the pressure in a manner previously determined by the author. Pressures upwards of 4000 atmospheres may be thus measured.—The application of iodine in the analysis of alkalies and acids, by C. F. Walker and D. H. M. Gillespie. The reaction between iodine and hydroxides of the alkalies and alkaline earths in hot solution is regular and complete under analytical conditions, not being appreciably affected by the mass action of considerable excesses of iodine. The reaction is best applied in analysis by titrating the alkali with an excess of iodine, removing this excess by boiling, and estimating the iodine in the residue.—Some new tertiary horizons discovered near Punta Arenas, Chile, by A. E. Ortmann. These beds, examined by Mr. J. B. Hatcher, represent two new horizons different from and older than the tertiary beds known as Patagonian, containing a marine fauna completely new to science.—A biotite-tinguaite dike from Manchester-by-the-Sea, Essex Co., Mass., by A. S. Eakle. This dike cuts through the augite-syenite of Gales rock near Manchester. It is six inches wide, and exposed for twenty feet. It is very difficult of access, and is only exposed at low water. The rock has a greenish-grey colour and a slightly greasy lustre, like tinguaites and rocks rich in nepheline. Small phenocrysts of felspar are visible in the somewhat compact ground mass, and also much magnetite, mixed with biotite, occurs in brownish-black patches, giving the rock a mottled appearance.

Wiedemann's Annalen der Physik und Chemie, No. 12.—Genesis of the electric spark, by B. Walter. The author mounts a long sensitive plate on a little car moving on rails and driven by a falling weight. The discharge from an induction coil is so timed that at least two sparks are recorded. The negatives show that each spark consists of several successive discharges in the same direction, at intervals of $2 \cdot 7 \times 10^{-4}$ secs. The spark is invariably preceded by brush discharges, and in places where the spark is bent, a small brush-like appendage appears, showing that the spark changed its direction in consequence of too large a resistance.—Genesis of the point discharge, by E. Warburg. When a needle-point is mounted in the centre of a metallic sphere and charged to a certain minimum potential, a continuous discharge passes from the point to the sphere. The author finds that the discharge sets in about 0·007 seconds after the potential has attained the proper value.—Properties of the stratified brush discharge in the open air, by M. Toepler. When the current intensity of an influence machine discharge is raised from zero to a high value, the discharge, at first an ordinary brush discharge, takes the form of sparks, and is eventually converted into a stratified "brush light arc," showing white kathode light, scarlet positive light, and anode glow. This is another proof of the essential identity of open-air and vacuum discharges. If the gap is very small, only the spark discharge can be produced.—Tuning-plates as a substitute for tuning-forks at high pitches, by F. Melde. Small square Chladni plates, say 5 cm. wide and 0·5 cm. thick, give high notes whose pitches can be safely calculated from their dimensions. They can also be experimentally determined by the author's resonance method, being made to transfer their vibrations to a rod whose length is adjusted until distinct nodes are formed, made visible by sound. Notes of pitches up to 30,000, and quite inaudible to most ears, can thus be produced and studied.

The Quarterly Journal of Microscopical Science (November) contains papers on the development of the pig during the first ten days, the structure of the mammalian gastric glands, certain green (chlorophylloid) pigments in invertebrates, a larva in the metanauplius stage, and the nephridia of the Polychæta (Part ii.).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 19.—"'Nitragin' and the Nodules of Leguminous Plants." By Maria Dawson, B.Sc. (London and Wales.) Communicated by Prof. H. Marshall Ward, F.R.S.

A study of the nodules found upon the roots of leguminous plants has led the author to an unhesitating confirmation of the parasitic nature of both the filaments and the bacteroids contained in these organs. The filaments, it was found, have no such constant relation to the nucleus of the cells, as was represented by Beyerinck in 1888. By plasmolysis of the root-hairs, the infection tube is shown to have grown into the hair, and not to correspond with the primordial utricle of the hair, a result which proves that Frank was mistaken in regarding the tube as formed from the contents of the hair mingled with fungal protoplasm. By staining with aniline blue and orseillin these tubes and the filaments in the cells were shown to consist of strands of straight rodlets, lying parallel to the longer axis of the filament, and embedded in a colourless matrix. This matrix does not consist of cellulose, chitin, or any form of mucilage. The swellings upon the filaments occur at places where the rodlets have become heaped up, and at such places the filaments eventually burst, liberating the rodlets, whilst they themselves remain as pointed portions, directed towards each other in the cells. After liberation from the filaments, the rodlets become transformed into X, V, and Y-shaped bacteroids. This variety of shape does not occur when these organisms are cultivated outside the plant on a solid medium, but in liquid pea extract, the change from straight rodlets to "bacteroids" occurs in a few days. By cultivating these organisms in drop cultures under constant observation with high powers, these rodlets are seen to multiply by division into equal, or sometimes slightly unequal, halves. By this method the author hopes also to determine whether the change in shape arises from fusion of two or more individuals or by branching. Their multiplication by division leads to the conclusion that these organisms are members of the Schizomycetes; whether or not they are true bacteria must, however, still be undecided until the final stage in their life-history has been fully followed.

The X, V, or Y-shaped bacteroid, when once formed appears to be incapable of further growth. These organisms are aerobic in character, their power of fixing atmospheric nitrogen is to be tested in connection with their growth on silicic acid gelatin.

Commercial "Nitragin" consists of minute micrococcus-like bodies, all straight and immobile. They multiply rapidly on gelatin media, and in pea extract become converted into "bacteroids" as well as straight rods. Nitragin does consist of the tubercle organism, and as a result of the inoculation of either seeds or soil with it, tubercle formation takes place. Crossing of kinds supplied for different genera and species is quite successful within the tribe Vicieæ. In order to test the possibility and conditions of direct infection of the roots, seedling peas, starting both before and after germination, were grown in sterile tubes, by which means the whole plant was kept under control. This method showed that direct infection of quite young radicles is tolerably certain, also of older roots, provided the conditions under which germination occurred are maintained after infection.

In order to secure infection it is not necessary that the organism should pass through the soil, and the age of the root-hair at the time of infection seems to be without effect upon the result. An accumulation of CO_2 round the roots is not the cause of failure in direct infection.

The addition of nitragin to soils rich in nitrates appears to be inadvisable, but a supply of it to soil poor in nitrates results in an increased yield, though better results are obtained if instead of nitragin, nitrates be added to the soil.

Royal Meteorological Society, December 21.—Mr. F. C. Bayard, President, in the chair.—Captain A. Carpenter, R.N., gave an account of the hurricane which caused so much devastation in the West Indies in September last. The cyclone, passing eighteen miles south of Barbados, swept over the southern half of St. Vincent Island, then took a north-west direction towards Aves Island, its rate of progression being about seven and a half miles per hour. From here it pursued a northerly course for 450 miles, passing between Puerto Rico and the Windward Islands. It then swerved to the north-west for 600 miles, when it re-curved to the north-east. Its diameter was eighty miles as it approached Barbados, and 170 miles after leaving St. Vincent. The actual storm-centre (in which the force of the wind greatly increased) was only thirty-five miles in diameter until St. Vincent was passed, but after that the strength of the wind extended to 170 miles from its centre. The diameter of the calm vortex, or "eye" of the storm, was not less than four miles. The storm was accompanied by very heavy rainfall, the amount at St. Vincent being about 14 inches in the twenty-four hours ending at 9 a.m. on the 12th. The barometer at the Botanic Gardens, Kingstown, on the 11th, fell from 29·539 inches at 10 a.m., to 28·509 inches at 11.40 a.m., a fall of 1·03 inches in 1 hour 40 minutes. In Barbados 11,400 houses were swept away or blown down, and 115 lives were lost; and in St. Vincent 6000 houses were blown down or damaged beyond repair, and 200 lives lost.—Mr. W. H. Dines read a paper on the connection between the winter temperature and the height of the barometer in North-western Europe. From an examination of the records of the barometer and temperature at several observatories, extending over many years, the author is of opinion that the winter temperature at a place in Western Europe has no connection with the height of the barometer at that place, and that in winter it is just as likely to be cold when the barometer is below the average, as when it is above the average.

Manchester.

Literary and Philosophical Society, December 13.—Mr. J. Cosmo Melvill, President, in the chair.—Dr. G. H. Broadbent described some microscopical observations he had recently made in the development of a Rotifer (*Philodina microps*) obtained from an infusion of bicycle mud. Two days after the organism was found the ovum was extruded, and was under observation for two days, when it was lost. On the following day another ovum was discovered, and the stages of development were observed day and night (with only seven hours' intermission) for four days, at the end of which period the organism emerged from the ovum fully formed.—Description of a new genus and species of Hymenoptera (*Liaba balteata*) from Chili, by Peter Cameron. The description is based on a single male specimen, which is undoubtedly closely allied to the genus *Nomadina* of the family *Trigonalidae*. This family the author proposes to divide into two tribes, *Trigonalinae* and *Nomadinae*, the former containing the genus *Trigonalis*, and the latter the genera *Nomadina* and *Liaba*.—Vestiges of primitive man found near Todmorden, by Dr. J. Lawson Russell. In July last the excavation of a curious "ring barrow" at Blackheath, near Todmorden, Yorkshire, was undertaken by Alderman Crossley and Messrs. Wilkinson and Lowe, of Todmorden, which resulted in the finding of the remains of several cinerary urns. The work of excavation was continued in November by Dr. Russell, who found a number of other urns, four of which, together with the various objects found with them—bone pins, a bronze knife, whetstones, beads of resin, lignite, pot and bone, and also several small vessels enclosed in the urns, of the kind usually known as "incense pots"—have been carefully restored by Messrs. Standen and Hardy, of the Manchester Museum. The urns, which were exhibited at the meeting, are all of different patterns and variously ornamented. The paper was illustrated by about fifty lantern slides prepared from photographs mostly taken on the spot, and showing the position of the urns *in situ* prior to removal, the disposition in the circle of the various objects found, and other features of interest.

Edinburgh.

Mathematical Society, December 9.—Dr. Morgan, President, in the chair.—The following papers were read:—Systems of circles analogous to Tucker circles, part ii., by Mr. J. A. Third; Cantor's history of Mathematics, vol. iii. part iii. (concluding): a review with special reference to the *Analyst* controversy, by Prof. G. A. Gibson.

Paris.

Academy of Sciences, December 19.—M. Wolf in the chair.—The President delivered his annual address, and gave a short account of the work of the Correspondants and Associates deceased during the past year. The prizes for the year 1898 were awarded as follows: the Grand Prize of the Mathematical Sciences to M. Émile Borel for his memoir on the part played in analysis by divergent series, M. Maurice Servant being awarded an honourable mention. The Bordin Prize was not awarded; the Francœur Prize was awarded to M. Vaschy, and the Poncelet Prize to M. Hadamard. In Mechanics, the Extraordinary Prize of 6000 francs was divided between MM. Baude, Charpy, Thiébaut, Ravier, and Moissenet; the Montyon Prize awarded to M. de Mas for his researches on the resistance of water to moving boats; a Fourneyron Prize to M. Bourlet, another being divided between MM. Carvallo and Jacob, and an honourable mention to Mr. Sharp. In Astronomy, the Lalande Prize is given to Dr. S. C. Chandler for his researches on the variation of latitude and on variable stars, M. Chofardet receiving an encouragement; the Damoiseau Prize is given to Prof. George Williams Hill for his numerous astronomical memoirs, the Valz Prize to M. P. Colin, and the Janssen Prize to M. Belopolsky. In Statistics, the Montyon Prize is awarded to M. Alfred des Cilleuls, M. Martial Hublé receiving a very honourable mention, and M. Paul Vincey an honourable mention. In Chemistry, the Jecker Prize is divided between MM. G. Bertrand, Buisine and Daniel Berthelot, Dr. C. A. Schott receiving the Wilde Prize. In Mineralogy and Geology, the Vaillant Prize is awarded to M. Cayeaux; and in Botany, the Desmazières Prize to M. G. Battista de Toni, the Montagne and La Fons-Melicocq Prizes not being awarded; but M. le general Paris and Dr. Ledoux-Lebard receive encouragements. In Anatomy and Zoology, the Thore Prize is given to M. Pantel for his contributions to the knowledge of parasitic organisms and their relations with the host, and the Savigny Prize to M. Courtière for his researches on the marine fauna of the east coast of Africa. In Medicine and Surgery, Montyon Prizes are received by MM. Widal, Sécard, Bard, Poncet and Bérard. Mentions are given to MM. Le Double, Variot, and Kirmisson, the Barbier Prize being given to Dr. J. Comby, the Bréant Prize to M. Phisalix, the Bellion Prize to M. Castaing, and the Baron Larrey Prize to MM. Regnault and de Raoult. The Godard Prize is divided between MM. Motz and Guiard, the Mège Prize between MM. Labadie-Lagrave and Félix Legueq, and the Lallemand Prize between Mr. E. P. Allis and M. Thomas. In Physiology, the Montyon Prize for experimental physiology is awarded to M. Tissot, honourable mentions being accorded to MM. Dassonville, Lesbre, Reynaud and Mlle. Pompilian, the Pourat Prize to MM. Courtade and Guyon, and the Philipeaux Prize to M. Moussu. In Physical

Geography, the Gay Prize is given to M. Sauvageau. Of the general prizes, the Leconte Prize is not awarded this year, M. Fremont receiving the Montyon Prize (unhealthy trades), Mme. Curie the Gegner Prize, M. Émilio Damour the Delalande-Guérineau Prize, M. Chaffanjon the Tchihatchef Prize, M. Édouard Branly the Houllevigue Prize, M. Félix Bernard the Saintour Prize, M. Munier-Chalmas the Estrade-Delcros Prize, and M. Merigeault the Laplace Prize. The following prizes are divided: the Jérome-Ponti Prize between MM. Guichard and Lemoult, the Cahours Prize between MM. Hébert, Metzner, and Thomas; M. Blanc receiving an encouragement, and the Kastner-Boursault Prize between MM. André Blondel and Paul Dubois and M. Paul Janet. The Rivot Prize is awarded to MM. Mérigeault, Defline, Le Troquer, and Gérin.

AMSTERDAM.

Royal Academy of Sciences, November 26.—Prof. Van de Sande Bakhuyzen in the chair.—Prof. Beyerinck, on a contagium vivum fluidum, causing the spot-disease of tobacco leaves. This disease, also known as the mosaic disease of tobacco leaves, may be inoculated into healthy plants by injecting into the stem, near a bud, sap pressed from infected plants. The active virus passes completely through the pores of very dense porcelain, and can even penetrate into agar by diffusion; therefore it cannot be a contagium fixum in the usual sense, but it must be fluid. Out of the tobacco plant it cannot be made to multiply; but in the dividing tissues of the leaf-rudiments and the meristems of the buds it multiplies freely and over a great extent. A very small drop of the porcelain filtrate can render all the leaves of the infected plant entirely covered with spots, and the sap of these leaves would be sufficient for the contagion of an unlimited number of healthy plants. The virus is destroyed by boiling at so low a degree as 90° C.—Prof. Bakhuis Roozeboom, on the phenomena to be observed on the solidification of liquids, consisting of two tautomeric forms. In the case of equilibrium being established between these forms at the temperature of solidification, these phenomena have been treated by Bancroft. A new deduction was given for those cases in which solidification takes place at temperatures at which no equilibrium can be established any more in the liquid, and specially when supposing that one passes from the region of equilibrium through two regions of one-sided equilibrium to the region of non-equilibrium. All the various consequences of slow and quick heating and cooling may be graphically represented.—Prof. Van der Waals deduced from the phase equation for a mixture, given by himself, the laws for Δ_v (the volume contraction on mixing under constant pressure) and Δ_p (the pressure contraction on mixing in given volume), and compared the results, obtained by himself, with the observations of Kuenen and others in the case of mixtures of carbonic acid and methyl chloride. According to Amagat, Δ_v would be $=0$, and according to Dalton's law, $\Delta_p=0$. The results, arrived at by the author, may briefly be summed up as follows: Δ_v is small all along the course of the isotherm, and the amount may be considered a magnitude of the same order. On the other hand, Δ_p follows a course equal to the deviation from Boyle's law, and when the volume is small it approximates infinity.—Prof. Van Bemmelen presented for publication in the *Proceedings* a communication by Mr. F. A. H. Schreinemakers, entitled, "Equilibriums in systems of three components, variation of the temperature of solution of binary mixtures by the addition of a third component."—Prof. Van der Waals, on the errors that may be committed in the determination of the molecular weight from the vapour density in consequence of the deviations from Boyle's and Gay-Lussac's laws.

DIARY OF SOCIETIES.

MONDAY, JANUARY 2.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—On Safety Explosives: Oscar Guttmann.
VICTORIA INSTITUTE, at 4.30.—The Physiography of the Thames Basin: Prof. Lobley.

WEDNESDAY, JANUARY 4.

GEOLOGICAL SOCIETY, at 8.—Geology of the Ashbourne and Buxton Branch of the London and North-Western Railway. Part I. Ashbourne to Crakelow: H. H. Arnold-Bemrose.—The Oceanic Deposits of Trinidad, W.I.: J. B. Harrison and A. J. Jukes-Browne.
SOCIETY OF ARTS, at 7.—Hands and Feet: Prof. F. Jeffrey Bell.

FRIDAY, JANUARY 6.

GEOLOGISTS' ASSOCIATION, at 8.—The Glaciers and Fjords of the Bergen District, Norway: Horace W. Monckton.
QUEKETT MICROSCOPICAL CLUB, at 8.

BOOKS RECEIVED.

BOOKS.—Das Kleinebuch von der Marine: G. Neudeck and H. Schröder (Kiel, Lipsius).—The New Gulliver: W. P. Garrison (N.Y., Marion Press).—Practical Photographer, Vol. ix. (Lund).—Die Kulturgewächse der Deutschen Kolonien und ihre Erzeugnisse: Prof. R. Sadebeck (Jena, Fischer).—Das Geotektonische Problem der Glarner Alpen: A. Rothpletz, Text and Atlas (Jena, Fischer).—Studien über Säugethiere: Dr. Max Weber, Zweiter Theil (Jena, Fischer).—Sewerage: A. P. Folwell (N.Y., Wiley).—A Text-Book of Physiological Chemistry: Prof. O. Hammersten, translated by Prof. J. A. Mandel, 2nd edition (N.Y., Wiley).—Annals of Coal Mining: R. L. Galloway (*Colliery Guardian* Office).—Fossil Medusæ: C. D. Walcott (Washington).—On the Study and Difficulties of Mathematics: A. de Morgan, new edition (Chicago, Open Court Publishing Company).—Truth and Error: J. W. Powell (Chicago, Open Court Publishing Company).—Lectures on Elementary Mathematics: J. L. Lagrange, translated by T. J. McCormack (Chicago, Open Court Publishing Company).—The Fishes of North and Middle America: Drs. Jordan and Evermann, Part 2 (Washington).

AN EVOLUTIONAL POLEMIC.

Organic Evolution Cross-examined; or, Some Suggestions on the Great Secret of Biology. By the Duke of Argyll, K.G., &c. Pp. vi + 201. (London: John Murray, 1898.)

IT has always appeared a mystery to the writer of this notice why the phenomena of life should be dealt with by some men of science and by certain philosophical writers in a totally different spirit to that in which other groups of natural phenomena are considered and discussed. It is true that we know less about life than about other phenomena—it is true that the organic world is full of unexplained mysteries. Equally certain is it that the living organism can accomplish physical and chemical feats by processes which we are now ignorant of, and which we cannot at present imitate. But it is not obvious why because a particular department of knowledge, by virtue of its inherent difficulties and intricacies, happens to be in a different phase of development from other branches of human inquiry, that the whole domain of organic nature should be detached and delimited, and put on quite a different plane to any other department of science.

Anthropologists might offer a reasonable explanation of this difference of attitude by an appeal to the history of the development of natural knowledge. The early observers of nature and the writers of the ancient cosmogonics were not impressed by the slow and orderly course of the inorganic world in the same way that they must have been familiar with their organic environment. The facts and laws of physical science required something beyond mere casual observation for their elucidation, and the manifestations of these laws became impressive only when they reached the dignity of cataclysms. On the other hand, these writers were constantly being brought into contact with the living world in a hundred ways that had a more or less direct influence on their everyday lives. They must have noticed the plants and animals of the districts which they inhabited; the individuals of their own and other races must have been of more direct importance to them than the unobtrusive sequence of non-vital phenomena. It is not to be wondered at that in the ancient cosmogonies the living world should have been regarded in a different light to the world of "dead" matter, and a special mode of origination invoked. In brief, there has arisen a set of ideas which are even broader than "anthropocentric," and which might fairly be designated *biocentric*, and it is these ideas which, consciously or unconsciously, permeate the work now under consideration and all similar productions.

The Duke of Argyll will no doubt disclaim any such severance of vital and non-vital phenomena. In certain passages he states somewhat explicitly that he wishes it to be understood that he deals with nature as a whole in this cross-examination of evolution. But it will be evident to those who have followed the course of thought in this field, that this latest contribution from the doughty opponent of Darwin and Spencer and Huxley and Wallace is nothing but a compromise between the ancient biocentric system and the newer ideas of the order and sequence of nature. It is a kind of eviscerated Bridgwater Treatise with an aggressive binding, and with the honest and plain teleology of the writers of those famous old volumes replaced by the word Plan with a capital P. If we are not mistaken, there was a period in the author's literary career when he scouted the idea of evolution in any form. Be this as it may, he now tells us that he accepts "the leading idea of development" (p. 98), and he even goes so far as to say that he holds this idea "to be indisputably applicable to everything, and especially to organic life." The same statement is repeated in other forms elsewhere in the book (p. 189, for example). The Duke apparently prefers the word "development" to evolution. There is a subtle distinction here which the ordinary reader might overlook, and which it is therefore desirable to point out. Evolution has become associated with development through external causes controlled by, and in co-operation with, causes resident within the organism. Such, at least, is the idea which the writer has always associated with organic evolution. Development on the other hand, is associated with a process of spontaneous growth by virtue of an internal agency only. This appears to be the burden of the Duke of Argyll's tale as told in the three essays composing the present work, which essays have been reprinted, with slight alterations, from the *Nineteenth Century*.

This notion of an internal force of development implanted in the organism by an external agency is a very venerable dummy. The Duke has tried to furbish it up with a fresh coating of paint, but evolutionists will, I am afraid, not consider the new garniture sufficiently attractive to claim their attention. The old figure is still there, and the dents made by the sticks thrown at it by such skilled marksmen as Huxley and Weismann are too deep to be effaced. We find, for example, on page 155, that an essential feature of the creed of the "mechanical evolutionists" (as interpreted by the author) is "the internal directing agency or force, which always pursues a definite line of growth, so that all the demands of the completed structure must have been present from the beginning, &c." This is considered by the Duke to be a necessary consequence of the belief of the evolutionist that the development of the germ is to be explained by "processes of ordinary generation." Why, it may be fairly asked, are biologists to be so constantly reminded in wordy essays that the characters and attributes and properties of organisms must have been potentially present from the beginning of life? The whole case of the biocentric school amounts to this, and nothing more. So all the characters of a complex mineral must have been potentially present in the material atoms of which it is composed; and if there is an internal directing agency in the case of a "procreated" germ, there is just as much an internal directing agency in the mineral compelling a definite crystalline structure and chemical composition. We have never heard of any essayist taking the writer of a mineralogical treatise to task because he had failed to indicate to his readers that the structure and composition of minerals were to be explained by innate properties conferred in accordance with a prearranged plan.

We have dealt so far with these essays in their constructive aspect, but they have also a destructive side;

and here we must in fairness to the author point out that he makes some good points out of Mr. Spencer's change of view with respect to the efficiency of natural selection. The whole of the first essay is in fact a kind of merry-making over Mr. Spencer's abandonment of that excellent child of his own creation, the term "survival of the fittest." We can safely leave the Duke in the hands of the veteran author of the "Synthetic Philosophy," but in so doing it may be well to indicate that many—perhaps we may say the majority of biologists in this country—have long ago parted company from Mr. Spencer on this question of the enhanced importance of "direct equilibration," and the subordinate position assigned to "indirect equilibration" in his later writings. When, therefore, evolutionists are withered with the reproach of being "mechanical" by the noble author of these three essays, *nous autres* can take comfort from the thought that it is those who in America are called the "Neo-Lamarckians," who are expected to realise the grossness of their conceptions.

The results of attempting to recast the old idea of "creation" in the mould of the modern theory of evolution are just those results to which all attempts at reconciliation appear to lead. What these results are can only be briefly indicated here; but if, as a study of mental attitude, the philosophical student will take the trouble to compare the destructive with the constructive side of the essays, he may find much material for his instruction. For surely it is instructive to find a writer using weapons for the demolition of an antagonist without apparently being aware that these same weapons are equally destructive when applied to his own position. The Duke is acutely critical in the first essay about Mr. Spencer's phraseology. He quotes with approbation Mr. Darwin's views about explanations which are good for everything in general, being good for nothing in particular (pp. 58-60). Every man of science will join hands with the Duke on this point. But after having indulged in such exceedingly great rejoicing over the abandonment of the hateful expression, "survival of the fittest," and all that is implied thereby, the author, in a later essay, lets us into the secret of his own view of the developmental process. It is all contained in the internal directive agency; it is—

"the kind of causation which is conspicuous in the preconceived Plan, in the corresponding initial structure, and in the directed development of vital organs as apparatuses prepared beforehand for definite functions" (pp. 192-193).

Now, as far as natural and physical science has any voice in this matter, it may be equally well said that everything that happens in the universe is in accordance with a preconceived plan. But why offer this as an explanation especially to be invoked in the case of vital phenomena? It must be equally true of gravitation which causes an avalanche to overwhelm a village, or of an earthquake or volcanic eruption which destroys a city. It is precisely of that order of "explanation" which is good for everything in general, and therefore for nothing in particular. In other words, it may be the statement of a general truth or it may not—the point is one that is outside the scope of scientific inquiry—but it explains nothing, and it leaves us precisely where we were before. Curiously enough, the author tries to make Huxley responsible for this kind of explanation with respect to the vertebrate skeleton—

"a Plan, laid down from its beginning, in its originating germs, with a prevision of all its complexities of adaptability to immense varieties of use. There must have been a prevision for these uses in certain elements and rudiments of structure, and in certain inherent tendencies of growth which were to commence, from time to time, the new and specially adapted structures" (pp. 161-162; also p. 120).

This is surely doing violence to Huxley's teaching; we can call to mind no passage in his works which bears this interpretation. We ask the Duke in fairness to Huxley to reperuse the fifth chapter of the second volume of Darwin's "Life and Letters."

The importation of ultra-scientific notions into the doctrine of evolution leads the author into all those other quagmires in which others have floundered before him. The summary of the Darwinian hypothesis, on pp. 60–61, is a travesty; the conception of variability, on pp. 108–109, is a totally inadequate statement of the actual state of knowledge; the reiteration of the epithets "mindless," "fortuitous," "haphazard," &c., as applied to variation, is an impeachment of Darwin's views which has been made over and over again, and which has been met over and over again. The attempt to hurry up the course of evolution, in order to meet the limits of time imposed by certain arguments from the physical side, leads the author to accept "discontinuous variation" or development *per saltum* (pp. 122–125). It may be of comfort to the Duke to know that Mr. Francis Galton will go some way with him here. But the analogy between the rapidity of individual development in some cases, such as in metamorphosis, and the rapidity of organic evolution, which is put forward as an original idea (pp. 120–124), appears to the writer to be a false analogy. The Duke's idea of discontinuous variation is given (p. 148) in the following words:—

"It is conceivable that species might be really as constant and invariable as we actually find them to be, for some long periods of time—embracing perhaps centuries or even milleniums—and then suddenly, all at once, evolve a new form which should be equally constant, for another definite time to follow."

This may be conceivable, but we should like to have some evidence of its probability. It involves not only a sudden departure or "sport" on the part of the individual offspring, but the simultaneous and similar aberration of all the offspring of a particular generation. Even the much-abused "mechanical evolutionist" has never made such a draft as this upon the resources of the speculative faculty. The old "internal developmental force" was in the minds of its supporters a respectable kind of agency that might be expected to come into operation when the exigencies of external conditions required it. But here we have a suggested mechanism of development which makes one shudder to think what might happen if there were the very slightest hitch in the adjustment between the characters of the new form, which appeared when the proper moment had arrived, and the external conditions under which the alarum, as it were, went off.

The discussion of rudimentary organs from the author's point of view (p. 162 *et seq.*) is one of the best illustrations of the effect of introducing ultra-scientific "explanations" into the domain of natural science that will be found throughout the book. These organs are not vestigial, but prophetic. Such a rudiment

"may be where it is—simply because it indicates an original direction of growth, or of development, which was made part of the vertebrate Plan from the beginning of the series, for the very reason of its potential adaptability to an immense variety of purposes. Moreover, the arrest of such tendencies of growth, at a given point in the series, may well have been part of the same Plan from the beginning" (pp. 175–176).

The general public, who have hitherto been accustomed to consider the essence of the theory of evolution to be contained in the statement that man is descended from a tailed ancestor, will no doubt hail this statement of the Duke's with acclamation, because the rudimentary tail (which is discussed on p. 157) may after all be only "an arrested tendency of growth." The other logical alternative, that it is a preparation for a tail to be developed by generations yet unborn, is quite legitimate from this point of view, but the author will doubtless not insist upon this deduction. Similarly the rudimentary teeth and pelvic limbs of whales, which are also somewhat fully considered, are not necessarily vestigial in the sense of being the remnants of structures that were at one time functional. These rudiments are likewise to be regarded as "arrested tendencies of growth," or else as predetermined preparations for the transformation of whales into land animals. Honestly we prefer the Darwinian explanation—even though we have to face the difficulty of the electric organs of the Torpedo.

We have discussed these essays in the spirit of controversy because they are purely controversial in character. They have been considered also at greater length than their scientific importance warrants. Strictly speaking, it is difficult to see what class of readers are influenced by writings of this kind ; certainly not working biologists of any school of thought. But the unlimited hospitality extended by the editors of high-class popular magazines to essayists of the calibre of the author of the present work, shows that such writers have the public ear, and it seems desirable to let the public know that the authority which is wielded by these knights of the pen is not conferred by those whose special studies in the field of biology might be reasonably supposed to give them the right of conferring such authority. There are some minds that may be satisfied with the word "Plan" as an all-sufficient explanation of natural mysteries yet unsolved. Like "the blessed word Mesopotamia," it may convey much comfort to such minds; but the earnest seeker after scientific truth will not be deluded, and he will still go on groping his way towards a knowledge of the processes by which the universe has been evolved by the only legitimate methods of observation, experiment, induction and deduction. It may be that, as Darwin long ago suggested, a definite set of characters undergoing selection may by inheritance tend to go on varying in the same direction, and so give to the course of development an impetus as though from some internal agency. But this agency would be only apparent, and not real in the sense of being a special entity. It would be a necessary consequence of heredity combined with other properties of living organisms which are "internal" in the same sense that crystalline form is due to the play of internal forces, and in no other sense. If, as the recent investigations of Prof. Karl Pearson seem to show, there is a tendency on the part of a race to undergo change in a definite direction, this tendency is the necessary consequence of correlation between fertility and other characters of the organism. To say that the laws of inheritance are the expressions of a preconceived Plan may be a statement of pious opinion, but as a scientific explanation it is quite devoid of value.

R. MELDOLA.

THE TIDES POPULARLY AND PROPERLY TREATED.

The Tides and Kindred Phenomena in the Solar System. By Prof. G. H. Darwin, Plumian Professor of Astronomy, Cambridge. Pp. xviii + 342. (London : John Murray, 1898.)

WHEN a man of unequivocal scientific eminence lays aside the technicalities which have assisted him along the path of important investigations, and attempts to reveal as much as may be of his subject to the wide public who cannot understand mathematical processes, the result is certain to be at least interesting. And especially is this so in the case of a subject at once so fascinating and so perplexing as that of the tides. A phenomenon of such evident significance in the economy of the globe, of such important influence on the interests of maritime communities, must necessarily have been under observation from the earliest times. Naturally the conscientious pre-Newtonian philosopher could not do more than recognise a more or less indefinite connection between the periodic alternations of sea-level and the positions of the moon and sun. And if his mind happened to be of that type which trusts more readily to speculation than to accurate observation, his theories were even less enlightened in a corresponding degree. Even after the genius of Newton had laid a foundation of rational hypothesis, the theory which remained with little modification or development until a comparatively short time ago, was one which on many essential points was absolutely contradicted by facts. Now this is the theory of which a rather inadequate description is included in some popular works on astronomy, whose most conspicuous failing in general is that they attempt to cover a far wider range than is really practicable. However that may be, a short chapter in a work of this character was practically the only place where information on tidal phenomena was to be found in a popular form, with the exception, of course, of Lord Kelvin's admirable popular lectures. In consequence, the subject of the tides is perhaps the one about which, more than any other, the most widespread misapprehension exists, even among persons who are otherwise fairly well informed. The present work therefore fills a manifest need, and Prof. Darwin is certainly right in thinking "that there are many who would like to understand the tides, and will make the attempt to do so, provided the exposition be sufficiently simple and clear." His dictum, that "a

mathematical argument is, after all, only organised common sense," is indisputable, but so far from making the task undertaken in any way easier, it really emphasises the enormous difficulty. But Prof. Darwin has avowedly taken pains to render an intricate subject intelligible, and it will probably be generally agreed that he has achieved an unqualified success.

In publishing in book form the lectures which were delivered last year at the Lowell Institute, Boston, Massachusetts, the author has been distinctly well-advised to recast their form, and to eliminate all traces of the lecture-room. It is surely evident that there is one style appropriate to the platform and another to the essay, and that the two are of necessity mutually incompatible. It appears very unfortunate that the habit of publishing lectures in the form in which they have been delivered is becoming so prevalent. The result is that a little trouble is saved on the part of the author, always more or less to the detriment of his work. Is it easy, for example, to imagine a more irritating book than Tyndall's "Sound"? No doubt that is an extreme case, but the personal form of address is always objectionable to the reader, and ought to be eliminated.

As soon as one begins to examine the book in detail, one is struck by the excellence of Prof. Darwin's judgment in the choice and arrangement of his subject-matter. A liberal and comprehensive interpretation is placed upon the scope of tidal and kindred phenomena, so that a wide field of recent investigation is surveyed. But cognate branches and developments are always displayed in due order and significance of relation, and digressions, as they may appear to be at first sight, will be found in reality to be in perfect harmony with a continuous purpose.

The book begins where physical inquiry ought always to begin, in methods of observation : this course has the further advantage that the reader is not dismayed by difficulties at the outset. The construction and use of gauges for recording marine tides having been explained, the study of the changes of level in lakes is introduced in the second chapter. These Seiches, as they are called, constitute a distinct and exceedingly interesting phenomenon, which has not hitherto received the recognition it merits. Most readers, we fancy, will find much that is novel in this account. Dr. Forel's work on the subject was begun about a quarter of a century ago, but his researches, carried out on Lake Geneva with remarkable skill, have only been imitated elsewhere within the last year or two. There can be no doubt that highly important results will follow from the systematic application of Forel's methods which has been begun on Lake George, in New South Wales, and on the great lakes of North America. Not only will an appreciative description of Dr. Forel's work with those instruments of his own invention, the Plemyrameter and the Limnimeter, be found in this chapter, but also an excellent account of Mr. F. Napier Denison's application to this case of Helmholtz' theory of the waves generated at the surface of separation of two layers of fluid in relative motion. In dealing with the peculiar behaviour of the waters in tidal rivers, Captain Moore's work in observing the "bore" on the Tsieng-Tang-Kieng is described, and illustrated by reproductions from photographs.

At this point Prof. Darwin introduces an historical sketch, in composing which he has had the happy idea of levying contributions from his colleagues at Cambridge in the form of extracts from the early philosophical and mythological writers of such nationalities as Chinese and Arabic. Only after so much by way of introduction does he attack the mechanical theory. Admirably lucid chapters deal with the statics of the tide generating force and the deflection of the vertical. This provides an opportunity of describing his own researches with the bifilar pendulum on lunar gravity, of which this popular account is most welcome. This in turn leads to a short discussion of those seismological problems which are now attracting wide attention. The distortion of the earth's surface is also discussed as a disturbing factor in the problem of the direct measurement of the tidal force. The famous equilibrium theory of the tides is next examined, its value being insisted on as a statement of the statical conditions of the problem. But Prof. Darwin, unlike most of his predecessors among the popular writers on the subject, does not stop at this unsatisfactory stage, but goes on to consider the hydrodynamics of the tide-wave Prof Darwin's treatment of free and forced waves in canals in different latitudes, and of tides in lakes and land-locked seas, leaves no ground for criticism, although it is impossible but that the unmathematical reader will find great difficulty in following the reasoning which the mathematician apprehends through the medium of differential equations. Any one who has fairly well mastered the foregoing chapters should have little difficulty in understanding the one in which Prof. Darwin expounds the great modern method of harmonic analysis, though here again it is scarcely possible for any but the mathematician to realise that this powerful theory leads to a unique solution of the problem, or, in other words, that it has any sounder foundation than juggling empiricism. A clear insight ought to be gained into the method by which tidal observations are reduced and made to provide the raw material for the tide-predicting machine. The practicability of tide prediction having been realised, it only remains to discuss the degree of accuracy which has been attained. This naturally leads to a consideration of the discrepancies, and the effects of wind and barometric pressure and the variation of latitude are discussed as disturbing factors. Thus the end is reached of that section of the book which deals with the subject in its more direct aspect.

It is impossible here to give any detailed account of the remaining contents of the book, although they are of absorbing interest and eminently capable of popular treatment. In masterly chapters Prof. Darwin examines the effects of tidal friction, and discusses those particular cases in which they seem to have been most clearly manifested. The chapter on the possible equilibrium figures of a rotating mass of liquid is a good example of the author's judgment in the arrangement of his material, beginning as it does with the more easily understood experiments of Plateau, and leading up to Poincaré's remarkable work. The Nebular Hypothesis as given here in outline by Prof. Darwin does not strain the limits of conceivability as it commonly does when expounded by less able writers, but is brought well within the bounds of rational probability. An excellent summary of those

researches which have led to a definite and final conclusion as to the constitution of Saturn's rings, brings the whole work to a fitting termination.

The diagrams and illustrations, though not very numerous, are generally good and clear, with the possible exception of Fig. 23, which seems to need more explanation than is given. The bibliographical notes, which are appended to every chapter, give most valuable and copious reference to the original authorities. Prof. Darwin's book ought to be read by "all those whose minds are in any degree permeated by the scientific spirit" (preface): it is certain to excite the interest and appreciation of all such, and not least of the mathematician, in spite of the fact that there is not a mathematical symbol from one end to the other.

W. E. P.

FLORA OF ROUMANIA.

Conspectul Florei Romániei. By Dr. D. Grecescu. Pp. xvi + 835. (Bucharest: Tipografiea Dreptatea, 1898.)

THIS is a valuable addition to our knowledge of the floras of the Balkan States. Prof. Grecescu's book supersedes Branza's "Prodromul Florei Romániei," which so far has been the only comprehensive work on the flora of Roumania. Branza enumerated 2100 species, of which Grecescu admits 1875 as "good." These figures refer to Roumania, exclusive of Dobrudsha. Grecescu includes, of course, the latter, and records 2450 species besides 550 varieties. This very considerable increase is partly due to the addition of the Dobrudsha flora, partly to the admission of not a few of Schur's very questionable species and of other "species minutæ," but mainly, no doubt, to the more complete collections which were at the author's disposal. The author evidently worked under considerable difficulties. He had not only to accumulate the bulk of the material on which his work rests, but was also obliged at the same time to build up, as it seems, a general herbarium of European plants for comparison. It is only fair to mention this in order that we should not criticise too severely shortcomings which are inevitable under such conditions.

The book consists of two parts, of which the first contains the Conspectus proper, or the enumeration of the species found within the borders of the kingdom of Roumania, preceded by a synoptical table of the classes and orders; whilst the second part deals with the general physiography of the country and the principal vegetations and floras of Roumania. The author follows in the arrangement of the orders on the whole the system adopted in Nyman's "Conspectus Floræ Europeæ." Why he deviates from it in certain cases is difficult to understand, if it is not partly to suit his key of orders; but when he subdivides, for instance, the "Embriogene Dicotyledóne Apetale Unisexuate" (*i.e.* the unisexual Apetalæ) into "Angiosperme" and "Gymnosperme," including Gnetaceæ in the former, then he shows such a disregard of modern nomenclature and the results of modern taxonomy, that at least an attempt of explanation ought to have been made. In fact, it is always precarious to introduce taxonomic reforms of a higher order into local floras, and the author would have done far better if he had stuck right through to Nyman's "Conspectus."

The introductory chapters of the first part ("Clasificatiea generală" and "Dispositiea familiilor naturale") are altogether the weakest part of the work, and might have been just as well omitted as being outside the scope of the book. The same applies to the short diagnoses of the tribes, subgenera and more subordinate groups which are dispersed through the enumeration of the species. As neither the genera nor the species are diagnosed, the result is an imperfect key which is useless to the beginner who does not know the genera, whilst the more advanced student who knows them is equally puzzled, as it does not carry him far enough.

The terminology is sometimes rather loose; for instance, when the perianth of Plumbagineæ and Primulaceæ is described as "herbaceous," or the terms used are obsolete, *e.g.* when "perisperm" is applied, as it was originally by Jussieu to albumen generally. Other errors, as the description of the capsules of Primulaceæ as pyxidia generally, are evidently mere slips. On the other hand, innovations like the subdivision of Gramineæ in two tribes, Eugramineæ and Maydeæ, are quite unjustifiable.

The author distinguishes three principal zones of vegetation in Roumania, *i.e.* an Alpine zone, a forest zone and a steppe zone, and he considers Roumania as forming part of a greater and natural phytogeographical region, the region of the Flora Dacica, with the Southern Carpathians as the principal focus, and extending to the Theiss in the west, the Dniester in the east, and the Danube and the Black Sea in the south and south-east. This section of the book is of considerable interest, and it is to be regretted that the author has not accompanied it by a *résumé* in French, English or German. We are sure there are many botanists who are interested in the constitution and differentiation of the Roumanian flora, but to whom a book written in Roumanian does simply not exist. They would certainly be thankful if the author would publish a translation or a comprehensive abstract of the second part of his book in one of the languages mentioned. Either, we venture to suggest, would gain very much by a careful revision which will convince him that, for instance, the number of endemic species admitted in the Alpine zone of the Flora Dacica (fully 31 per cent.!) is far too high, or that many of the so-called Mediterranean elements can hardly claim this designation.

O. Stapf.

OUR BOOK SHELF.

De Danske Barkbiller (Scolytidae et Platypodidae Danicae). By E. A. Lövendal. Pp. xii + 212; plates 5. (Copenhagen, 1898.)

In this work Mr. Lövendal, of the Copenhagen Museum, has written a most complete account of the Danish species of bark-beetles, a subject previously dealt with by him, principally with regard to its systematic side, in Meinert's "Entomologiske Meddelelser." No European family of beetles, relatively to its size, has given rise to a more copious literature, chiefly because of its important economic relations; and in Eichhoff's "Die Europäischen Borkenkäfer," we possess already an excellent treatise on the European species known at the date of that work.

While the present monograph follows, almost inevitably, the lines of Eichhoff's work, to which it constantly refers, it is, so far as its extent goes, a great advance on that book; for the author has spared no pains in achieving an exhaustive treatment of the subject, both by his own observations and by collation of what has been written by others.

Mr. Lövendal is artist as well as author, and is already well known as the illustrator of Schiödte's "De Metamorphosi Eleutheratorum." He has executed for the present work five plates, by the now almost disused method of line-engraving, which cannot be surpassed for beauty of style or accuracy of detail. The text is furnished with some eighty woodcuts, showing the burrows of these insects in bark and wood, and the whole book is printed in the most sumptuous manner.

Such a book, written entirely in Danish and on about fifty species of a single Coleopterous family, is for the very few. But it is worthy of more general examination as a monograph which in method, fulness and finish, leaves nothing to be desired. The publication of a work of this calibre would be, we fear, at present entirely beyond the resources of British entomology. W. F. H. B.

Through Arctic Lapland. By Cutcliffe Hyne. Pp. xi + 284. (London: Adam and Charles Black, 1898.)

WE have in this volume a very interesting account of the author's journey from Vardo Island, lying in the north-east corner of Norway, to Haparanda, in Sweden, situated at the head of the Gulf of Bothnia. Mr. Cutcliffe Hyne was accompanied by his friend Mr. Cecil Hayter, to whom he is indebted for the illustrations, which form an attractive feature of the book.

On arriving at Vardo, inquiries were made as to the best means of getting across the country, and it was found that the journey was an unheard-of undertaking in the summer months, the country being chiefly swamps, lakes and rivers. In winter it would have been comparatively easy, for the ground being hard, and the water frozen, there were recognised routes, and stations where relays of deer could be obtained.

However, the travellers were not to be daunted by the apparently hopeless look-out presented to them, and they persevered, with the result that they accomplished what they set out to do.

The journey is of particular interest, for this special route had never been taken before. The incidents described are numerous and exciting, and the life and customs of the nomad Lapp are well depicted. The chief means of subsistence of this Lapp is in the possession of large herds of deer; for not only does their milk, which is thick and syrupy, form part of his daily food, but he breeds them, and rears them for selling and killing. With regard to sledge-deer, it takes three years of severe training before they can safely be driven.

All through the book we are struck with the descriptions of the beauty of the vegetation, and also with the lack of wild life. The troublesome swarms of mosquitoes and flies form a special drawback for travelling in that part. Nothing of great scientific importance is disclosed, but much which will help those who wish to visit Arctic Lapland.

The New Gulliver. By Wendell Phillips Garrison. Pp. 51. Jamaica, Queensborough, New York: The Marion Press, 1898.)

THIS is an amusing fantasy in which a shipwrecked graduate of Yale College is supposed to be cast upon an island, and to hold dialogues with a dapple-grey horse, which refused to acknowledge Prof. Marsh's *Orohippus* or *Eohippus* as its ancestors, and explained that there could be no moral sense without language; from which conclusion certain theological distinctions are drawn.

Converse of the Zeeman Effect.

I HAVE not seen it noticed that a converse action to the Zeeman effect should exist. A radiating atom in a magnetic field gives out circularly polarised light. A circularly polarised beam of light should cause a directed rotation of the electrons, so that the absorbing gas should be magnetised and exhibit magnetic force. If all the molecules in a c.c. of gas were caused to rotate their electrons in the same direction, it would possess quite a considerable magnetic moment. It is very improbable that the action of a circularly polarised beam of light would control the motions to such an extent as that: but it is quite possible that, if a circularly polarised beam of sunlight were passed through a strongly absorbing gas, it would magnetise it to an observable extent. The same effect would probably exist in any medium in which absorption was principally due to syntony and not mostly due to viscous actions. Hence I would expect some effect with absorbing substances like fuchsine. It is doubtful whether lampblack, iron, or other metals have a sufficiently syntonous absorption to exhibit the effect.

My assistant Mr. Thrift is engaged in trying the experiment, but in the meanwhile I thought it might be of general interest to point out that such an effect should exist.

Flow of Water.

I TOOK occasion, in the course of a paper on "The Character of Fluid Motion," read on December 14 before the Liverpool Engineering Society, to give the following reply, which I promised to Prof. Osborne Reynolds's letter, which appeared in your issue of September 15 last.

"Prof. Reynolds's comments may be placed under three headings:

"(1) An expression of disagreement with what he takes to be my views on the subject of the light border.

"(2) An explanation of the light border or bands adjacent to the solid boundary.

"(3) The expression of the belief that the water charged with air bubbles does not in any way represent the motion of the fluid itself.

"In the first place the criticism of Prof. Reynolds is based, apparently, upon a misconception of the statement in my first paper (*Trans.* Inst. Naval Architects, vol. xxxix. p. 151).

"In his letter he states as my views 'that with water in sinuous motion and air bubbles as indices of the manner of motion, the light bands adjacent to the surfaces of the solids, which show absence of bubbles adjacent to the solid, prove that the once air-charged water has not been carried by sinuous motion sufficiently near to the solid surface to displace the initially adjacent water; and hence prove that the sinuous motion does not extend up to the solid surface.' What I really wrote was, however, very different to this, viz. that the result of my observations had led me to the conclusion that the 'clear border line represents a condition of parallel flow of layers of water past the skin of the obstacle, or the sides of a pipe, in which a state of shearing exists, while outside this, in the darker portion, the water is in a state of sinuous motion, which corresponds to the state of the higher velocity of water.'

"These two statements are really very different because it was not my own belief that the once air-charged water never reached the surface, but that when it did so, the air has been removed from it for reasons which I gave (*Trans.* Inst. of Naval Architects, vol. xl. p. 45), where I stated that although I had 'purposely avoided introducing unnecessary speculations in trying to account for the observed facts, it does, however, seem that the clear film may be partly accounted for as the result of inertia, which allows the heavier water to reach the side of the submerged body, and partly from the fact that the velocity being less there, the pressure might be greater, and so the air being excluded from the portion where the water is moving with

parallel motion; whereas, it is entangled and broken up in the portion where the sinuous motion of the water occurs.'

"It will be observed that this explanation is to a certain extent the same as that subsequently given by Prof. Osborne Reynolds in the letter to NATURE, from which I have quoted, and to which I refer under heading (2).

"The experiments of Prof. Reynolds, which he cites himself, are entirely different from those of which I have given an account, and seem to me to have but very little bearing upon the behaviour of water in the conditions under which my experiments were conducted.

"With regard to the differences of state in the water in the light band, I will not trespass on your time with a repetition of the arguments which I have already published, and which have not hitherto been answered, but I would point out that the experiments you have seen to-night form a most striking method of putting the theory to the test by actually placing liquid under the condition of the thin border, and in obtaining when this is done, results which are absolutely different from those which were given by the thick film or sheet of water. This is one of the strongest possible arguments in favour of the views which I have advanced, inasmuch as the results of the experiment seem to have surprised some of the greatest authorities on the subject.

"Coming to (3), I would first remark, though it has never been distinctly claimed, that the water charged with air actually represented real stream-line motion, in my first paper it was stated that 'there was no difference whether the smallest quantity of air was present, or so large a quantity as to render the slide opaque, as the general behaviour of the flow of water was practically unaffected by the presence of the air.'

"Though this remark only applied to the general nature of the results obtained, the experiments brought out very strongly, I believe for the first time, various points which had long been known to the naval architect, but which had not been actually made visible to the eye. Prof. Osborne Reynolds, however, states that 'air bubbles are the most misleading bodies that can possibly be chosen to indicate the lines of motion in a fluid in sinuous motion.' This remark led me to consider the very appropriate experiment of trying the effect of first taking the air-charged water upwards and then taking it downwards under the same conditions. Inasmuch as the air in one case was trying to rise upwards through the water, which is moving in the same direction, whereas in the other case it is trying to move in the opposite direction, it is perfectly certain that if there was much difference in the flow owing to the presence of air, it would become marked under those circumstances.

FIG. 1.

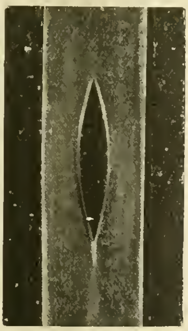

FIG. 2.

"The two photographs, Figs. 1 and 2, represent the results of this experiment, and I venture to think that no one would be able to tell from the photographs themselves where the air-charged water was flowing upwards or where it was flowing downwards. This, I think, shows in a very striking way the comparatively small effect which the presence of air under *suitable* conditions, has upon the flow of the water, and it is quite contrary to that which Prof. Osborne Reynolds seems to anticipate."

The truth of the whole matter appears to be this, that as far as Prof. Osborne Reynolds has dealt with the behaviour of air in water, it has been under conditions represented by plates suddenly immersed or moving through still water, in which case air has been in a state of bubbles of large size, whereas in my own experiments, the air has been broken up into very minute bubbles. The behaviour in the two cases has been as different as that of a mass of water, say from a bucket, thrown through the air, and the finely-divided particles of moisture in a fog or mist. The effect of viscosity makes all the difference in the two cases. As, however, I have never had an opportunity of seeing Prof Osborne Reynolds's experiments, and as he has never witnessed mine, perhaps his disagreement with me is, after all, only another illustration of the old fable of the chameleon.

University College, Liverpool, December 21, 1898.

Etherion, a New Gas?

SOME months ago the discovery of a new gas, by Mr. C. Brush, was announced by nearly all the scientific periodicals of the world, which was said to be endowed with quite extraordinary properties; as, for instance, density one ten-thousandth of hydrogen, molecular velocity and heat conductivity hundred times that of hydrogen!

It seemed strange to me that such tremendous assumptions should be based on no more convincing arguments than the experiments (Mr. Brush's) reported therein, on the relative increase of condition of heat in rarefied air, when glass powder, contained in the same vessel, was being heated, and I was waiting eagerly for the publication of the original account (Mr. Brush's), since it struck me that all observed phenomena could be explained by the well-known properties of water vapour.

I was glad to learn afterwards, from a paper in the *Chemical News* (November 4, p. 221), that this is also the opinion of Sir William Crookes, undoubtedly the greatest authority in this kind of research.

Now the original paper (Mr. Brush's) appeared in *Science* for October 14. It has been already the subject of a severe criticism by "A Physicist" in the *Chemical News* (December 2, p. 277), as it does not contain indeed any further argument for Mr. Brush's hypothesis. I do not think it superfluous, however, to warn in NATURE, too, against an excessive credulity in this matter, and to point at some facts not yet emphasised sufficiently by other sceptics.

First I must mention, for the sake of those readers who are not sufficiently acquainted with these things, that the conduction of heat by gases, when not disturbed by convection currents, is independent of the pressure, until this comes down to several millimetres of mercury; then it begins to decrease, at first very slowly, then faster, until it becomes nearly proportional to the pressure, at the highest rarefactions; and the differences of conduction in various gases, very marked at higher pressures, are much less at pressures of several millionths of an atmosphere.

These facts, which are in strictest accordance with the kinetic theory of gases, as I have shown in the *Phil. Mag.* (August 1898), have been investigated besides by other observers very carefully, also by Mr. Brush himself, and form the object of a very interesting paper of his in the *Phil. Mag.* (January).

Mr. Brush found that the conduction of heat is increased very much at high exhaustions in respect to other gases at corresponding pressures, when glass powder is heated (but remaining always much smaller than at normal pressures), and he infers from this that a gas of enormous conductivity is given off by heated glass powder.

Now to me the main point seems to be—how did Mr. Brush measure these low pressures? By an improved form of the Macleod gauge, which seems to be very suitable for dry gas, but of course, like every Macleod gauge, is quite unfit for gases where moisture or other condensable vapours are present, since then it indicates only the partial pressure of the not condensable gas. He did not use any drying agents, since they absorbed the gas in question, therefore the indications of the gauge are of no value whatever as to the total gas pressure.

When Mr. Brush measured a gas pressure of 0·38 millionth, and found the conduction to be about forty times that of dry air at this pressure, he may have had in reality a pressure of 0·38 millionth of air, and besides a pressure of 20 millionth of

water vapour, which of course would be sufficient to account for that large effect.

Sir William Crookes mentions that, according to his experiments, water vapour produces a greater conduction at very low pressures than air; but I decidedly disbelieve the difference to be in any way similar to the numbers given by Mr. Brush, in consequence of a reasoning mentioned at the end of my *Phil. Mag.* paper, and I think the simplest explanation to be afforded by this source of errors vitiating the pressure indications.

It is no mere hypothesis but a certain fact that water vapour is being evolved by heated glass, and probably many other substances. Sir William Crookes gathers quite a number of arguments for it from his own researches, amongst others spectroscopical proofs. The same opinion was put forward by Kundt and Warburg, who were led to it by the very same sort of experiments on conduction of heat as Mr. Brush's, which they made as early as 1875 (*Poggendorff's Annalen*, 156, p. 177). Further investigations on the hygroscopical properties of glass, and on means for partially removing them, were published by Warburg and Ihmori (*Wiedemann's Annalen*, 27, p. 481).

I cannot prove, of course, that there is no new gas evolved, but I maintain that whatever facts Mr. Brush has put forward as an evidence for its existence, can be explained quite simply by the presence of water vapour (perhaps also other condensable vapours), which he seems to have overlooked. I do not think it necessary to go into details, and to analyse more thoroughly the—rather fantastic—speculative part of the paper, where scarcely any statement is not open to serious objections.

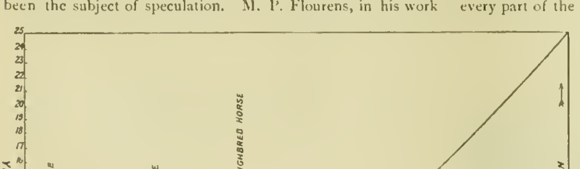
Although thus I differ from Mr. Brush very much in respect to the interpretation of his recent results, I think his elaborate experimental investigations, as reported in his *Phil. Mag.* paper, to be of great value for the theory of these phenomena; certainly it would be very desirable that he might carry on those researches, as he promised there to do.

M. SMOLUCHOWSKI DE SMOLAN.

Vienna, University.

The Curve of Life.

THE relationship between the duration of adolescence and potential longevity in different species of mammals has repeatedly been the subject of speculation. M. P. Flourens, in his work



on "Human Longevity," made the ratio between the two periods as 1 to 5; Buffon had previously concluded that it was as 1 to 7. In neither case were the data sufficiently numerous and trustworthy to make these figures generally accepted. In the course of some investigations on the variability of the adolescent period in different breeds of the same species among certain well-known mammals, I have satisfied myself that a relationship exists between the duration of growth and the length of an animal's natural life; although it is evidently not of the kind suspected by the older writers. It may be stated as follows:—The ratio of length of adolescence to length of life in the shortest lived mammals is proportionally less than it is in longer lived mammals. For example, the period of growth and development of the domestic mouse is, according to my informant, a breeder of these small rodents, about three months. Its natural lifetime is four years. In other words, the mouse may be expected to live about fifteen times its adolescent period as a mature animal. The Arab horse, according to a well-known authority, arrives at maturity in about eight years, its lifetime is about forty years; that is to say, the animal lives four times the length of its adolescence as an adult. Man, on the other hand, who only completes his growth by the union of the sternal epiphysis of the clavicle to its shaft at the age of twenty-five, has, after passing his fiftieth year, or "the middle arch of life," to use Dr. Farr's phrase, only another twenty-five years' expectation of life. His potential longevity accordingly foreshadows a period of maturity not greater than twice the length of his youth.

I have obtained, through the kindness of numerous correspondents interested in breeding and rearing of farm and other domestic animals, the approximate lengths of these two periods in a few well-known mammals; and the accompanying diagram shows the relations between growth and longevity among the same animals plotted as a definite curve. This result was entirely unexpected by me, and it may be interesting to some of your readers.

W. AINSLIE HOLLIS.

Hove.

The Alleged Destruction of Swallows and Martins in Italy.

IN your issue of December 22, 1898, I read the report of a conference held by the Society for the Protection of Birds, at which a paper was read on the decrease of swallows and martins coming to England, giving, as a reason for this decrease, the netting of thousands of these birds on their arrival at the Italian shores, and their subsequent consumption as food.

May I venture to remark that, during a residence of some years in Italy, I have never once seen a swallow, or any member of its family, exposed for sale, and that I have never known, or heard of, an instance of their being netted in the manner described, though I am well acquainted with nearly every part of the Peninsula.

Since reading the above mentioned accusation against Italy, I have asked several Italians whether they knew of such a practice, and am informed that it is simply non-existent, the swallow being, perhaps, the one bird in this country which is regarded with a kind of sentiment by all classes, as the harbinger of spring.

Swallows, moreover, do not arrive on these coasts in a state of exhaustion, and to net them would be no easy feat.

A few isolated cases of the cruel method of capturing them with artificial flies may occur, but not more so than in England.

The Italian may be ruthless in his destruction of other birds, but is certainly not a destroyer of the *Hirundinidae*.

Of the similar charge made against the French, I am not in a position to judge, but I imagine that the cause for the decrease of the *Hirundinidae* in England may lie in quite another direction, and may be attributable to some equivalent decrease of their favourite insects in our islands, or in some atmospheric and climatic change. Italy, I am convinced, is not responsible in any way for it.

RICHARD BAGOT.

Roma, December 27, 1898.

RADIATION PHENOMENA IN THE MAGNETIC FIELD.

IN the spring of 1897 the scientific world became indebted to Dr. Zeeman for the observation that when a source of light is placed in a strong magnetic field the spectral lines of the light emitted by that source suffer

marked modification. The general type, or characteristic type, of this modification is that when the slit of the spectroscope views the sources of light across the lines of magnetic force, each spectral line becomes a triplet, of which the middle line has the same wave-length as the original line; whereas the side lines of the triplet have wave-lengths, respectively, a little longer and a little shorter than that of the unmodified line, the difference of wave-length being proportional to the strength of the magnetic field. Further, the central line has its vibrations parallel to the lines of force, whereas the side lines of the triplet have their vibrations perpendicular to the lines of force. Thus, if the axis of the magnetic field is horizontal, so that the lines of force are horizontal, and if the slit of the spectroscope looks horizontally across the lines of force, then in the central constituent of the triplet the vibrations are horizontal, while in the side lines the vibrations are vertical. Thus the central line is plane polarised, and the side lines are also plane-polarised, but in a perpendicular plane. This is the typical phenomenon when the light is viewed across the lines of force. When the light is viewed along the lines of force—that is, through axial holes pierced in the pole-pieces of the electromagnet, the modification is different. In this case, instead of a triplet with plane polarised constituents, we are presented with a doublet, having circularly polarised constituents. That is, each spectral line is broken up into two lines of slightly different wave-length; one constituent being circularly polarised in one sense, and the other in the opposite sense. As before, the difference of wave-length, and therefore the separation of the constituents of these doublets in the spectroscope, is proportional to the strength of the magnetic field for each line, but differs in amount for the different spectral lines.

In order to fix the ideas of those who are not familiar with this department of physics, the phenomena described above are represented diagrammatically in Fig. 1. Thus at A the upper single line is supposed to represent a bright spectral line of some substance when the radiating source is not influenced by the magnetic field. This line becomes converted into three distinct lines, that is a triplet, as shown underneath at A′, when the source of light is subject to a strong magnetic field, and the radiation takes place across the lines of force. If N be the vibration frequency of A, then the vibration frequencies of the members of the triplet A′, into which A is converted, are N − n, N, N + n, where N is a small quantity depending on the strength of the magnetic field. On the other hand, when the source of light is viewed along the lines of force a bright spectral line, B, becomes converted into a doublet, B′, consisting of two distinct lines which are circularly polarised in opposite senses. The constituents of the triplet A′ are, on the contrary, plane polarised, the direction of vibration in the middle line being horizontal, while that in the side lines is vertical.

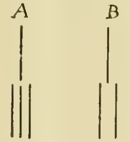


Fig. 1.

The foregoing are the phenomena demanded by the simplest form of theory, and they are the phenomena actually yielded by experiment in the case of the vast majority of spectral lines. Many lines, however, when carefully examined in a sufficiently strong magnetic field, yield phenomena which differ in a remarkable manner from the simple theoretical expectation described above. In some cases the middle line of the triplet becomes resolved into a pair of lines so that the triplet becomes a quartet, while in other cases each line of the triplet becomes a pair, and thus a sextet is produced; and in some cases the side lines of the triplet become resolved into triplets, while the middle line becomes a doublet, and then an octet is produced, and so on. Thus generally, when the light is viewed across the lines of force, we may say a single spectral line becomes resolved by the magnetic field into a system of lines consisting of a central part bordered by two side parts. The central part may consist of one or more lines, and is plane polarised, while the side parts may each consist of one or more lines, and are also plane polarised in a plane at right angles to the plane of polarisation of the central part.

On account of this opposite polarisation the central part may be quenched and the sides examined separately, or *vice versa*, by means of a nicol's prism, and consequently the existence of this plane polarisation enables us to scrutinise the phenomena much more closely and effectively than would be otherwise possible unless, indeed, a magnetic field of any desired strength could be produced so as to obtain complete and wide separation of the various constituents of the modified line. But it is not possible at present to produce a magnetic field for working purposes of a strength exceeding 30,000 to 40,000 C.G.S. units. Hence the polarisation is of importance for purposes of observation. The best way to take advantage of it is not to use a nicol's prism (which lets through only one of the two plane polarised beams), but to use instead a double image prism, or a rhomb of doubly refracting crystal, placed before the slit of the spectroscrope, so that two images of the source are produced on the slit, one above the other (the slit being supposed vertical). Of these images one consists of light vibrating horizontally—that is, it consists of the light which forms the central part of the triplet A′ (Fig. 1), while the other image consists of light vibrating vertically—that is, the light which forms the sides of the triplet A′ when the magnetic field is excited. These two images on the slit give rise to two spectra in the field of view of the spectroscope, one above the other: one consisting of the lines which form the centres of the triplets, and the other of the lines which form the sides. This is shown in Fig. 2, where A represents a triplet as seen in the field of view, without the use of any nicol or double image prism, and A′ represents what is seen when a double image prism is used. The upper line in A′ represents the light vibrating horizontally, and is what would be seen if a nicol's prism were placed before the slit with its principal plane vertical; whereas the two lines below in A′ are formed by the light vibrating vertically, and constitute what would be seen were the nicol turned through a right angle. With the double image prism, however, the upper and the lower lines in A′ are seen simultaneously, and so a great deal of trouble is avoided, and much time is saved when the phenomena are being photographed. But the chief advantage of separating the middle from the side lines, as at A′ (Fig. 2), lies in the fact that in many cases the difference of wave-length of the middle and the side lines is so small, even in a very strong magnetic field, that the width of the lines causes them to overlap, and so obliterate the phenomena. It was for this reason that in the earlier experiments made by Dr. Zeeman, merely a broadening of the spectral lines was observed, and not a tripling. In fact, it was not until theory pointed out that tripling and plane polarisation should exist across the lines of force, that Zeeman interposed a nicol's prism, and found that the broadened line exhibited the polarisation required, and that the facts were not discordant with the theory. It is to be observed, however, as I have pointed out elsewhere, that the removal of the central part from the broadened line by a nicol properly interposed (so that

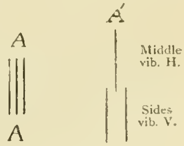

Fig. 2.

the broadened line now appears as a doublet), does not absolutely prove that the broadened line is a triplet with its components overlapped. It merely determines that the broadened line may be a triplet, and that the theory which anticipates the tripling may be correct. In order to place this matter beyond all doubt, it is necessary to so increase the strength of the magnetic field that the components of the triplet (if they exist) shall be completely separated from one another; and when this[1] is done, it is found that the tripling exists, but it is also found that many divergencies from the uniform expectation of theory (pure tripling) exist. Thus, as pointed out above, many lines under the influence of the magnetic field show as quartets, or sextets, or octets, or other modified form of the normal triplets. In the examination of these cases the double image prism forms a very valuable adjunct, as all the light polarised in one plane goes to form one image, while all the light polarised in the perpendicular plane forms the other image. The appearance presented in the field of view of the spectroscope by different types of lines, under these circumstances, is shown in Fig. 3. In this figure the lines of the upper row are formed by one image from the double image prism—that is to say, by the light vibrating horizontally, and correspond to the central members of the normal triplets; while the bottom row consists of light vibrating vertically, and represents the side lines of the normal triplets. Thus at A A′ we have the normal triplet, as expected by theory, with the central line, A, polarised in one plane, while the two side lines, A′, are polarised in the perpendicular plane. This type exists in the case of by far the greater number of spectral lines, and may be regarded as the general or normal type, if for no other reason than the frequency with which it occurs. The second type, shown at B B′, is a quartet in which, instead of a single middle line, we have two middle lines close together at B, with the two side lines at B′ as before. This type of quartet occurs in the blue cadmium line 4800, and in the blue zinc line 4722. At C C′ another species of quartet is shown; in this there are two middle lines also, but the separation of these is almost as wide as that of the side lines, so that the appearance presented to the eye when the double image prism is not used is that of two fine doublets, rather than the quartet appearance of the type B B′. This third type, C C′, occurs in the case of the sodium line D_1, the greenish-blue line of barium 4934, and many others. The fourth type, D D′, is a sextet of fine uniformly spaced lines, two of which correspond to each component of the normal triplet. That is, the central component is a doublet, and each of the side components is also a doublet. This type is represented by the line D_2 of sodium. The fifth type is shown at E E′, where the central constituent is a doublet, and each of the side components is a triplet. The distance between the components of the central doublet in this case is about the same as that between the central members of the side triplets. This type is represented in the yellow line of barium 5850. All the variations so far noted may be embraced in the general statement that each line of the normal triplet A A′ may itself become a doublet or a triplet.

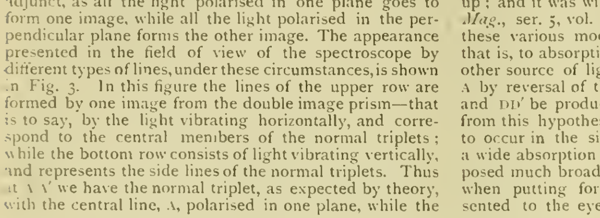

FIG. 3.

The question now of greatest importance is whether these various types of modification by the magnetic field are consistent with the theoretical explanations of the phenomena put forward by Larmor, Lorentz, and others? Naturally one must endeavour to reconcile facts and theory. If this reconciliation has not yet been effected, we must not hastily conclude that the theory is wrong, or even that it requires to be modified or patched up; and it was with this feeling that I put forward (*Phil. Mag.*, ser. 5, vol. xlv. p. 325, April 1898) the idea that these various modifications might be due to reversal—that is, to absorption in the outer parts of the spark or other source of light. Thus B (Fig. 3) might arise from A by reversal of the middle line, and so also might C C′ and D D′ be produced, and even E E′ might be intelligible from this hypothesis if we supposed double reversal to occur in the side components of the triplet A A′, and a wide absorption band to occur in the middle line (supposed much broader than the others). But (as I stated when putting forward this view) the appearance presented to the eye is not that of ordinary reversal, so that appearances are against the supposition that the modifications are due to absorption in the vapour surrounding the source of light. But still it is to be remembered that the magnetic field exerts a considerable influence on the source of light, and might alter considerably the appearance of an ordinary reversal. However, in order to test this matter, I observed many lines, which deviate from the normal triplet type, in a magnetic field of gradually increasing strength. The object of this was to determine if the separation of the lines forming the upper row in Fig. 3 (say, the doublet B or C) depended on the strength of the magnetic field. Thus, if the components of the doublet B remain fixed while the distance between the side lines B′ continues to increase as the magnetic field increases in strength, then we might conclude that reversal is not only a possible explanation by very probably the true explanation. But the components of the central parts B, C, D, do not remain fixed as the magnetic field increases in strength. On the contrary, the distance between the two lines B increases as the strength of the field increases; indeed, as far as rough observations go, the distance between the components of B or C, like the distance between the side lines B′ or C′, is proportional to the strength of the magnetic field. Similar remarks apply to the types D D′, E E′, &c. When the field increases in strength, the lines forming D separate from each other, and so also do the doublets D′, and the lines forming each component of the latter also separate, so that the sextet remains a system of equally spaced lines. On the other hand, when the field is reduced in strength the various lines close up till B, C, D, E each appears as a single line with B′, C′, D′ as narrow doublets—in fact, the normal triplet type is approached in appearance as the field is reduced.

It appears, therefore, that the explanation of the various modifications of the normal triplet type cannot be satisfactorily explained by reversal, and consequently these divergencies must be referred to the action of the magnetic field on the vibrating structure which emits the

[1] This was effected by the writer in October 1897, and triplets and quartets were then photographed directly without the aid of a nicol or any polarising apparatus whatever. (See letter to NATURE, dated November [illegible], 1897, vol. lvii. p. 173.) These photographs were shown at the November meeting of the Dublin University Experimental Science Association, at the December 1897 meeting of the Royal Dublin Society, and at the January 1898 meeting of the Royal Society of London; but it was not till April 1898 that they were reproduced in the *Philosophical Magazine* (5th series, vol. xlv. p. 325, plate xviii.).

radiation. Now the theory which indicates that a spectral line should be slit up into a pure triplet by the action of the magnetic field, assumes that the freedom of vibration is the same in all directions, and it is from this that the resolution into triplets occurs. This assumption is that which one most naturally makes in a first attack on a problem of this nature, but no one making it would be surprised if the facts did not turn out more complicated than the prediction of such a solution. For example, it is quite possible to conceive a state of affairs in which the magnetic field may constrain all vibrations to take place along the lines of force, in which case the side lines of the triplet would vanish; or, on the other hand, vibration in the direction of the lines of force might be impossible, in which case the central line of the triplet would vanish. Indeed, one is somewhat surprised that deviations of this kind from the normal triplet type do not more frequently occur. In fact, when I first examined the spectrum of iron, I hoped to find many deviations of this kind, but failed to detect any very marked difference between the behaviour of iron and other substances. This is not much to be wondered at when it is remembered that iron ceases to be magnetic at a comparatively low temperature, and, therefore, at the temperature of the spark of an induction coil, one should not expect its vapour to behave much differently from that of any other substance.

However, as already stated, the normal triplet type arises in theory because the orbit of the vibrating electron is supposed free from constraints and perturbations—that is, that movement is equally free in all directions. When constraints are imposed, or new forces arise which cause perturbations in the orbit, new frequencies will be introduced into the vibrating system. Thus if an electron, or an atom, or a particle describes an ellipse under a central force with frequency N, and if disturbing forces came into play which cause the apse line to rotate with frequency n, then, as Dr. Stoney[1] has shown, a spectral line arising from the original vibration of frequency N will become replaced by two others of frequencies $N + n$ and $N - n$ respectively. Again, if the disturbing forces cause a precessional motion of the plane of the orbit round a fixed line with frequency n, the original vibration of frequency N becomes replaced by three others of frequencies $N + n$, N, and $N - n$ respectively, and similar phenomena arise when other periodic disturbances occur in the orbital motion. We are prepared, therefore, to find that each line of the normal triplet may become itself a doublet or a triplet.[2]

The disturbing forces arising from the action of the magnetic field should increase with the strength of the field, so that if the distance between components of the doublet B or C or D or E (Fig. 3), which takes the place of the central line of the normal triplet, should increase with the magnetic field, as it is found to do by experiment. In fact, if the distance between the side lines of the normal triplet AA′ be written in the form $d_1 = k_1H$, where H is the strength of the field, and k_1 a quantity depending on the wave-length and other constants involved in the production of the particular line in question, then the distance between the components of the modified central component B, C, &c., may be written in the form $d_2 = k_2H$. Thus as the field increases in strength the whole system of lines into which any given spectral line becomes resolved, separate laterally from each other proportionately, as it were, according to a given scale Similar remarks, of course, apply to systems like DD′ and EE′.

Now in any particular case, such as BB′ for example, if the distance between the pair of lines B′ is

$$d_1 = k_1H$$

while the distance between the pair B is

$$d_2 = k_2H$$

there is apparently no reason why k_1 should be greater than, or less than k_2. Whether k_1 is greater than or less than k_2, must be determined by the action of the magnetic field on the system which produces the particular spectral line in question. Accordingly we are prepared to find that in some lines the components of the central line, as at B, shall be much closer together than the side components at B′, while in others, as at C, E and F, the distance d_2 is nearly equal to, or may be even greater than the distance d_1 between the side lines. Thus, once the production of a quartet of the type BB′ is explained, all the other modifications become intelligible. The case in which the components F are wider apart than the side lines F′ (so that the centre, as it were, encloses the sides) is merely the same phenomenon (only more accentuated) as that shown at BB′ where the separation d_2 is less than d_1. This point is mentioned here specially because in some cases the separation d_2 is actually greater than d_1, and it seems to be regarded as a difficulty of a much higher order than that in which occurs in the ordinary quartet, where d_2 is less than d_1.

Lines of the former type FF′, viz. that in which d_2 is greater than d_1, seem to have been first observed by MM. Henri Becquerel and H. Deslandres (see *Comptes rendus*, t. 126, p. 997, April 4, 1898) in the spectrum of iron, and subsequently Messrs. J. S. Ames, R. F. Earhart and H. M. Reese announced that they had observed the form GG′ (Fig. 3) in the spectrum of iron. In this type the side lines G′ coincide, or are not sensibly separated, while the components of the central part G are well separated.[1] (see *Astro. Phys. Journal*, vol. viii. p. 48, June 1898). The form in which this observation was described was calculated to startle, if not confound, the most firm believer in theory. It was said that these lines exhibited *reversed polarisation*—that is, that the polarisation of the centre is that which should occur in the sides, and *vice versa*. Stated in this way it is rather calculated to take one's breath away, but when stated as in the foregoing, it loses all special significance, viz. that it is merely a case of d_2 being greater than d_1, that is $k_2 > k_1$, or a quartet in which the distance between the horizontally vibrating constituents is greater than the distance between the vertically vibrating constituents. Stated in this way it falls into line with the other phenomena, and is reduced to the explanation of the doubling of any one individual member of the normal triplet.

Other similar modifications have been observed by MM. Becquerel and Deslandres, who appear to have examined the spectrum of iron very thoroughly as well as the bands of carbon and cyanogen. These bands they found to be unaffected by a magnetic field strong enough to sensibly split up the air lines.

Investigations demanding special attention are those of Prof. A. A. Michelson, both on account of his reputation as an original investigator and by reason of the nature of the apparatus which he employed. Working with his interferometer, Prof. Michelson concluded some years ago (*Phil. Mag.*, vol. xxxiv. p. 280, 1892) that the spectral lines themselves instead of being, as ordinarily supposed, narrow bands of approximately uniform illumination from edge to edge, are on the contrary in most cases really complexes, some of them being close triplets, and so on. This structure has never yet been observed by means of any ordinary form of spectroscope, and accordingly it has been suggested that it does not

[1] Dr. G. J. Stoney, *Trans. Roy. Dub. Soc.*, Vol. iv Series 2, p. 563, 1891. This is a very important paper when considered in connection with the above-mentioned magnetic perturbations of the spectral lines.

[2] These matters are treated in further detail in a paper by the present writer to appear in the forthcoming number of the *Philosophical Magazine*.

[1] I have not yet observed this type, nor do my photographs verify the conclusion of Messrs. Ames, Earhart and Reese, regarding the lines mentioned by them as belonging to this type. (This is further referred to in the forthcoming number of the *Phil. Mag.*)

exist in the light radiated from the source, but is imposed on the spectral lines by the apparatus used, namely, the interferometer. Be this as it may, the application of this instrument to the study of radiation phenomena in the magnetic field is highly interesting. In his first experiments Michelson merely observed a *doubling* of the spectral lines both along and at right angles to the lines of force (!), but subsequent observations proved that tripling occurred across the field of force, and that the constituents of the triplets were themselves multiple lines (see *Astro. Phys. Journal*, vol. vi. p. 48, 1897; vol. vii. p. 131, 1898; vol. viii. p. 43, 1898). But this is accompanied by the most surprising statement that the separation of the lines in the triplets produced by the magnetic field is independent of both the spectral line and the substance. In other words, that the separation is the same for all lines and all substances! Now, in all observations with ordinary grating or prism spectroscopes the separation of the components produced by the magnetic field varies very considerably for the different spectral lines of the same or of different substances. Even in the case of lines of nearly the same wave-length the difference is often very marked. The separation not only differs for different substances, but it is some complex function of the wave-length for any one substance. That the interferometer has led to such a law as that announced by Prof. Michelson, shows that there is some peculiarity of the instrument not yet taken into account—or else that by chance Prof. Michelson has happened to confine his observations to lines which give approximately the same separation; yet this latter could not be easily done. Be this as it may, Michelson has examined these phenomena by aid of another new instrument of his own design—the Echelon spectroscope (*Astro. Phys. Journal*, vol. viii. p. 43, 1898). With this instrument he states that the results previously obtained by aid of the interferometer, and the visibility curve, were confirmed. And this is striking, for if it confirms the general law stated by him in regard to the separation of the components, then the interferometer and the Echelon spectroscope are at variance with all other forms of spectroscope.

With apparatus which reveals structure or multiplicity in the ordinary spectral lines, it is to be expected that multiplicity would be readily revealed in the constituents produced by the magnetic field; yet in the case of some lines, the amount of finer structure revealed does not appear to be as great as that observed with a good grating, and this with other discrepancies require clearing up. If we suppose that an ordinary spectral line really consists of two or more very close lines, not separated in ordinary spectroscopes, and if we suppose that this multiplicity is produced by small perturbations caused by events inside the molecule, then it is clear that the further perturbations (if any) brought about by the magnetic field, may either increase, or diminish, or possibly reverse, those previously existing in the free field. And from this point of view the following most interesting observations made by Michelson (*loc. cit.*) become intelligible. "A very remarkable effect is observed in the case of the yellow copper line. This line without the field is a close double, the distance being 1/150th of the distance between the D lines, or 0·04 A.V. As the field increases the lines merge together without broadening, and with a strong field there is but a single narrow line."

"The behaviour of the yellow-green line of manganese is even more striking. The line is a quadruple line, just resolvable. In a weak magnetic field the light accumulates in the centre of the group, the lines becoming indistinct and merging together. In a strong field the quadruple band is reduced to a single fine line at the centre of the group."

In conclusion, it is necessary to mention briefly some ingenious methods which have been devised to exhibit the existence of the Zeeman phenomena in comparatively weak magnetic fields. The first of these chronologically was devised by M. Cotton (*Comptes rendus*, t. 125, p. 865) in 1897, and depends upon the fact that if a small sodium flame, A, be placed in front of a larger one, B, and viewed against it, the outer edges of the small flame appear dark. This arises, as is well known, from the absorption which takes place in the outer sheath of the smaller flame. If, however, the flame B be placed in the magnetic field, the dark border around A disappears. This arises from the fact that the magnetic field induces new periods of vibration in B (the side lines) which are not possessed by A, and therefore not absorbed.

The next experiment to be mentioned is one of special elegance, devised by Prof. Auguste Righi (*Comptes rendus*, t. 127, p. 216, 1898, and *Rend. della R. Accad. dei Lincei*, July 1898). If a plane polarised beam of light from a powerful source, such as an arc lamp, be transmitted through an absorbing vapour, such as a sodium flame, or sodium vapour in a tube, and if the light, after passing through the vapour, be transmitted through a nicol's prism, and then received on the slit of a spectroscope, a continuous spectrum will be observed in which dark lines occur corresponding to the absorption lines or bands of the vapour. If the analysing nicol be rotated till its principal plane is perpendicular to that of the polariser, then all light in the spectroscope will be extinguished.[1] Now suppose this to be so arranged, and suppose, further, that the absorbing vapour is between the pole-pieces of a magnet so as to be subject to the action of the magnetic field, and suppose that the light passes through this vapour along the lines of magnetic force by passing through axial holes pierced in the pole-pieces, then under these circumstances, if the magnet be excited, bright lines appear in the spectroscope corresponding to the absorption lines of the vapour. At first sight it appears as if the magnetic field caused the vapour to emit its own vibrations as if it were highly luminous. It is not so, however. The explanation is that the magnetic field so affects the vapour, that if it were self-luminous any spectral line appertaining to it of frequency N is converted into two other vibrations of frequency $N + n$ and $N - n$ respectively; and these two, along the lines of force, are circularly polarised in opposite senses, and consequently the vapour when cold possesses the power of absorbing vibration of frequencies $N + n$ and $N - n$. Now the beam from the electric arc passing through the vapour being continuous, possesses vibrations of frequency $N + n$ and also of frequency $N - n$. These vibrations in the arrangement, described above, are plane polarised, and any plane polarised vibration is equivalent to two opposite circular vibrations. The result is that the vapour absorbs one of the circular components from the rectilinear vibration $N + n$, and transmits the other. In the same way it also absorbs one of the circular component vibrations from the vibration $N - n$, and transmits the other. These transmitted circular components are very intense (having evidently half the intensity possessed by the arc light), and they cannot be extinguished by the analysing nicol, so they consequently appear in the spectroscope. If the magnetic field is not very strong, the vibrations $N + n$ and $N - n$ practically coincide with N, and what is presented to the eye is that the absorption lines of the vapour become bright when the magnetic field is excited. This can be observed in fields of very small intensity.

Prof. Righi mentions that the phenomenon observed in the foregoing experiment does not occur when the light traverses the vapour in a direction perpendicular to the lines of force. This is a result which differs from

[1] If a sodium flame be used as the absorber, then of course faint sodium lines will still remain. For this reason the sodium flame used should not be bright.

the theoretical expectation. For an emission frequency N of the vapour will now be converted, across the lines of force, into absorption frequencies $N+n$, N, and $N-n$. The first and last being for vertical vibrations, and the central one for horizontal vibrations. If, therefore, the plane of polarisation of the incident light (arc lamp) be inclined at any angle a to the vertical, its horizontal component will be absorbed by the vapour for the frequency N, and its vertical component for the frequencies $N+n$ and $N-n$. The other components will be transmitted, and being vertical and horizontal respectively, and not being of the same period, they cannot be extinguished by a nicol set to quench light polarised at an angle a to the vertical. When the incident light is polarised in a vertical plane, however, or in a horizontal plane, the analysing nicol can quench the transmitted light, and the lines do not light up in the spectroscope. The writer has found on trial that the expectation of theory is realised, and that when the polariser is inclined to the vertical the phenomenon takes place across the lines of force as in Righi's experiment along the lines of force.[1]

Many other interesting points deserve notice, such as Prof. G. F. Fitzgerald's theory connecting the Faraday effect with the Zeeman effect; but want of space compels us to close the present account of the work done in this field during the past year. We may just mention, in conclusion, that the Faraday effect in gases has been placed in strong evidence by an interesting experiment due to MM. Macaluso and Corbino (*Comptes rendus*, t. 127, p. 548, 1898), which depends for its explanation on the fact that the rotatory power of a substance increases enormously as the frequency of the transmitted light approaches that of an absorption band of the substance through which it is transmitted.

THOMAS PRESTON.

RECENT WORK IN COMPARATIVE MYOLOGY.

THE introduction of biology into medical education, productive of such good effects, has been in few departments more beneficial than in that of comparative anatomy; and we desire to call attention to the present aspect of one outcome of this, which appears to us a direct result of the adoption by the surgical anatomist of the comparative method, and to be full of promise for the future.

Our remarks are prompted by a paper which has recently appeared in the *Proceedings* of the Zoological Society, as the completion of an extensive study of the comparative myology of the terrestrial carnivora, by Prof. Bertram Windle and Mr. F. G. Parsons, a most laborious piece of work, involving the careful dissection of close upon one hundred individuals representative of the leading carnivorous families. Of desultory descriptions of the myology of individual mammals we have long had enough, and it is the merit of the two anatomists named to have attacked the subject in a thoroughly systematic manner, transcending that of most of their predecessors. Incorporating with their own extensive observations the sum of our previous knowledge, by carefully classifying the muscles, dealing with them in sets, and tabulating their relationships where necessary in a manner permitting of ready reference, they have now laid the foundation of a really comprehensive system of recording myological facts. The paper to which we refer is serial with others which its authors have published on the Rodentia and Marsupialia, either individually or together; and perusal of the series leads us to believe that in finally deciding the zoological position of some of the more anomalous mammalian forms the study of the muscles may yet play a not unimportant part. We welcome thus, for example, the conclusion of one of the authors that the Jerboas are allied to the Myomorpha as insisted upon by Winge; and the fact that in other respects they are in agreement with his recent work in the classification of the Mammalia, the value and importance of which has been by no means sufficiently appreciated in this country.

In having access to the collections of the Zoological Society, Royal College of Surgeons Museum, and other London institutions, our authors command a wealth of material unobtainable elsewhere, and they are thus enabled not merely to record facts of adult anatomy, but, by comparing individuals of species, to approximately determine the limitations of individual variation. Accurate observations, when systematically arranged, have a permanent value in the progress of science; and, confessing to an admiration of the laborious persistence with which our authors have persevered in their task, we sincerely hope they will continue it until each and every order of Mammals shall have been investigated.

REV. BARTHOLOMEW PRICE, F.R.S.

THE death of the Rev. Bartholomew Price, F.R.S., on Thursday last, deprives the University of Oxford of one who worked long and loyally for its welfare. He took a most active part in the business of the University and of his College, and on many occasions helped to further the interests of science at Oxford. For these labours and for his attractive personal qualities he will be long remembered by many old pupils and friends.

Dr. Price was born in 1818 at Coln St. Dennis, Gloucestershire, and was educated privately at Pembroke College, whence he obtained a first class in mathematics in 1840. He gained the University Mathematical Scholarship in 1842, and two years later was elected Fellow of his College. In 1844 he became tutor, and nine years afterwards Sedleian Professor of Natural Philosophy. In 1852 appeared the first volume of his elaborate work on the infinitesimal calculus, dealing with the differential calculus; the second, on the integral calculus and calculus of variations, was published in 1854; the third, on statics and dynamics of a particle, appeared in 1856; and the last of the four, on the dynamics of material systems, was published in 1862. This treatise obtained for him a considerable reputation in the mathematical world; but his principal work in life was practical, and he will be remembered rather as the active secretary of the University Press during the years of its first great activities after the death of Dean Gaisford, than as a Mathematical Professor. Prof. Price resigned the secretaryship of the Clarendon Press in 1885, when he was succeeded by Mr. P. Lyttelton Gell, who held the post till a few months ago.

Dr. Price was appointed Sedleian professor of natural philosophy at Oxford in 1853, and he only retired from his post in June last, upon attaining his eightieth year. The event was commemorated by a dinner, at which numerous old pupils and others showed the esteem in which they held their counsellor and friend. For many years, both before and after his appointment to the chair of Natural Philosophy, the greater part of the mathematical teaching of the University was in his hands. He was one of the public examiners in mathematical and physical sciences eleven times in twenty-four years, and his works on the differential and integral calculus, &c., were for long the recognised text-books.

Dr. Price was elected a Fellow of the Royal Society in 1852, and he served on the Council of the Society no less than five times. He also served on the Royal Com-

[1] Prof. Righi's elegant experiment was brought before the notice of the British Association in September last by Prof. S. P. Thompson, and three or four days afterwards, with kind permission, I made the observations here described in Prof. Barrett's laboratory in the Royal College of Science, Dublin.

mission to inquire into property and incomes of the Universities of Oxford and Cambridge. He was a Curator of the Bodleian Library, an honorary Fellow of Queen's College, a member of the governing body of Winchester College, and a visitor of the Greenwich Observatory. He was appointed Master of Pembroke College in 1891.

By his remarkable diligence and geniality, and his services in furthering scientific interests at Oxford, Prof. Price became a distinguished feature of his University, where his death will be deeply regretted.

NOTES.

SCIENCE is to be congratulated that two well-known workers for its advancement are included in the list of New Year honours. We refer to Prof. W. C. Roberts-Austen, who has been promoted from the rank of Companion of the Order of the Bath (C.B.) to a Knight Commandership (K.C.B.), and Mr. W. T. Thiselton-Dyer, who has been raised to the rank of Knight Commander of the Order of St. Michael and St. George (K.C.M.G.). Two distinguished members of the medical profession have had honours conferred upon them—Sir Henry Thompson receiving the dignity of a baronetcy, and Dr. Hermann Weber the honour of knighthood. Mr. J. F. Flannery, ex-President of the Institute of Marine Engineers, has also been knighted.

THE recent retirement of Sir John Evans from the Treasurership of the Royal Society, after a period of service of twenty years, has given an opportunity for Fellows of the Society to show their appreciation of the efficient manner in which he discharged the duties of his office. It is proposed to have his portrait painted in oil colours, and to hang it on the walls of the Society's apartments at Burlington House. This would be an appropriate form of recognition of the long association of the Treasurer with the interests of the Society. A number of subscriptions have already been received, and any Fellows of the Society who wish to contribute should send their donations to the Assistant Secretary.

A TELEGRAM from Sydney has been received at the Royal Society stating that the boring into the coral at Funafuti had been discontinued on reaching a depth of 1114 feet. An account of recent operations at Funafuti appeared in NATURE of November 3, 1898 (p. 22).

AT St. Petersburg, last week, a Pan-Russian congress of climatology, hydrology, and balneology was opened by the Grand Duke Paul, as president of the Society for the Preservation of Public Health, for the discussion of means of improving and better utilising the health resorts, bathing places, and mineral waters which now abound in various parts of the empire, especially in the Crimea and the Caucasus.

THE French Government is about to adopt precautionary measures against the introduction of the San José scale into France. Decrees will be issued prohibiting the importation of trees, shrubs and plants from the United States, and requiring an inspection of all fruits, fresh and dried, at the point of landing in France.

THE death of Dr. John Stillwell Schanck, emeritus professor of chemistry and hygiene in Princeton University, is recorded in *Science*. Dr Schanck was born in 1817, and began the practice of medicine at Princeton in 1843. In 1847 he was made lecturer in zoology at the College, and in 1856 was elected professor of chemistry, to which the chair of natural history was added in 1869. In 1874 the professorship was limited to chemistry, and from 1885 until he was made emeritus professor, in 1892, his chair was entitled chemistry and hygiene.

M. MAURICE LÉVY has been elected Vice-President of the Paris Academy of Sciences for the current year, in succession to M. van Tiegham, who passes to the presidential fauteuil.

IN the report of the meeting of the Kent Coal Company (*Standard*, December 24), the Chairman is stated to have said that "if there was coal in Kent it must affect that Company for good. If there was not, then every scientific man had been wrong. He did not think that could be." The Dover boring has certainly proved the presence of coal-measures in Kent, but no scientific man can say how far these underground coal-measures extend.

THE *Electrical Review* announces that a competition has just been opened by the Swiss Society of Chemical Industry for a treatise which shall be of service in aiding the development of the electro-chemical industry in Switzerland. A premium of 2000 francs (80*l*.) is being offered to the author of the work which shall be adjudged the best of those sent in. All competitors must send in their work by May 1, 1900, to Herr Dr. Henry Schaeppi, president, Die Schweizerische Gesellschaft für Chemische Industrie, Mitlödi, Switzerland, from whom full particulars of the competition may be obtained.

IT is announced by the *British Medical Journal* that an international congress on tuberculosis and the methods for combating it will be held in Berlin from May 23 to 27. The Imperial Chancellor, Prince Hohenlohe, will preside, and will be supported by an influential Committee, headed by the Duke of Ratibon and Prof. von Leyden. Five divisions of the subject have been agreed on: (1) propagation, (2) etiology, (3) prophylaxis, (4) therapeutics, (5) sanatoria. Each of these questions will be introduced by a short and concise address, so as to leave ample time for free discussion and debate.

THE twenty-sixth annual dinner of old students of the Royal School of Mines will take place at the Hotel Cecil on Friday, January 27. The chair will be taken by Mr. F. W. Harbord. Tickets may be obtained from Mr. H. G. Graves, 5 Robert Street, Adelphi, London, W.C.

MR. G. E. LUMSDEN informs us that he has been asked by the President of the Astronomical and Physical Society of Toronto to collect such confirmatory data as are accessible in respect of the contention that associated with certain lightning-flashes and displays of aurora, there are black or dark phenomena. He would be glad to obtain evidence upon this subject, and would be prepared to purchase, if necessary, photographs or lantern slides of lightning flashes, where black streaks or other phenomena are undoubtedly present. His address is The Parliament Buildings, Toronto, Canada.

SOME interesting facts with reference to the mining and minting of gold and silver are mentioned by Mr. Alexander E. Outerbridge, jun., in a paper published in the December *Journal* of the Franklin Institute. It is remarked that notwithstanding the excitement over the Klondike discoveries, the output from that region is insignificant when compared with the total product of the whole country. Statistics show that the State of Colorado alone added twice as much gold to the world's stock in 1897 as did the Klondike region, and several other States largely exceeded the Klondike output. As to the South African gold fields, American mining engineers who have been engaged in developing them, have computed from surveys of the ground and numerous assays of samples of ore taken from different localities and at different depths, that the gold contained in the ore in sight in the district known as the "Rand," or Witwaatersrand, amounts to the enormous value approximately of 800,000,000*l*., and at the present rate of production it will take half a century to exhaust these deposits, even though no further discoveries be made. Australasia and the

United States together produced more than one-half of the entire output of gold in 1897, and it is in these two countries that modern methods have been most largely adopted.

The Decimal Association has taken a leading part in educating public opinion, and in making known the advantages of the metric system. The system is used so extensively in scientific work that it is unnecessary to explain in these columns its claims for adoption. The strongest argument in favour of metric weights and measures is the fact that nearly all the leading civilised countries of the world, as well as nearly all our competitors in foreign trade, use them exclusively. From a table given in a pamphlet published by the Decimal Association, it appears that the countries which have already adopted the metric weights and measures represent a population of over 448 millions. Our consuls have almost unanimously reported in favour of the system; our chief Chambers of Commerce have passed resolutions in favour of it; in the new "British Pharmacopœia" the use of the system has been much extended; and numerous trade associations have given support to it; while in no single case has any body of wholesale or retail traders opposed its compulsory adoption. It is now especially urgent that an Act should be passed to make the change compulsory, and all who are interested in this important question are urged to become members of the Decimal Association, and to give it the benefit of their influence and co-operation. The Secretary is Mr. Edward Johnson, Botolph House, Eastcheap, London, E.C.

Reference has been made in these columns on several occasions to Prof. Grassi's work in tracing the propagation of malarial germs by mosquitoes. Further information is now brought to light by communications read before the Reale Accademia dei Lincei during the past month, and published in their *Atti*, vii. 9 and 11. Messrs. G. Bastianelli, A. Bignami and Grassi have now succeeded in tracing the development of the semilunar bodies in the medial intestine of *Anopheles claviger*, kept at a suitable temperature, after these insects had drawn blood from individuals affected by æstivo-autumnal malaria. They have also obtained spring fever by the sole agency of punctures of *A. claviger* in an individual not previously afflicted by malaria and living in a non-malarial locality. Most recently they have observed the later stages of the semilunar bodies in *A. claviger*, and have obtained capsules containing an enormous quantity of filiform bodies apparently non-motile, with one or two amorphous residual masses. The life-history of the malarial parasite is thus proved to be an authenticated case of heterœcism. Concurrently with these observations, Dr. Antonio Dionisi has studied the life-cycle of the endoglobular parasite of the bat, which appears to undergo a similar alternation of generations, the intermediary host being an insect. These conclusions agree with Ross's investigations on the malarial parasites of birds.

The discussion of the meteorological observations recorded at Trevandrum, under the superintendence of Mr. J. Allan Broun, during the years 1853 to 1864, is published in vol. x. part i. of the *Indian Meteorological Memoirs*. The observatory, which was established by the Maharajah of Travancore, was situated approximately in latitude 8° 31′ N., longitude 76° 59′ E. The observations were deposited at the Meteorological Office in London, and the Meteorological Council, recognising the high scientific value of the data, requested the Secretary of State for India, through the Royal Society, to undertake their discussion, which was agreed to, and the work has been ably carried out under the supervision of Mr. J. Eliot, Meteorological Reporter to the Government of India. We can only very briefly refer to a few of the valuable results obtained. The highest temperature observed was 94°·6, in March, and the lowest 59°·9, in December, giving a total range of 34°·7. The highest and lowest mean daily temperatures were 84°·5 and 70°·9, and the highest and lowest mean monthly temperatures were 82°·9 and 75° respectively. The greatest change in twenty-four hours was 5°·1, in May. One of the most noteworthy features of the meteorology of Trevandrum is the remarkable steadiness of barometric pressure; it is highest from January 11–15 (29·731″), it decreases slowly, but steadily, until the end of May, when it is 29·621″, and it increases during the remainder of the year. The absolute maximum of the diurnal range is ·132″, in February, and the absolute minimum ·099″, in July. The relative humidity is large in all months, varying from a minimum of 72·6, in February, to 86·8, in July. The annual rainfall varies considerably; the mean for thirty-nine years (1838 to 1876) is 64·4″. The mean for the three years of greatest fall was 27·7″ more, and the mean for the three years of least fall was 25·8″ less than the mean fall.

We have received a valuable quarto memoir by P. Jose Coronas, of the Manila Observatory, on the eruption of the volcano Mayon, which occurred on June 25–26, 1897. Mayon is the largest volcano in the island of Luzon, and a brief account is given of the principal known eruptions prior to 1897; but, with three exceptions (those of 1616, 1766 and 1800), these all belong to the present century. In a series of interesting chapters, Father Coronas describes the preparatory phenomena (including the earthquake of May 13), the beginning of the eruption, the ejection of lava, the rain of ashes and dust (which extended to about one hundred miles east of the volcano), the detonations and other subterranean noises, the storm on the volcano, and the end of the eruption. The memoir is issued from the private press of the observatory, and is illustrated by four plates and three figures in the text.

The native arithmetic of Murray Islands, Torres Strait, is described by the Rev. A. E. Hunt in the latest *Journal* (New Series, vol. i. Nos. 1 and 2) of the Anthropological Institute. The only native numerals are netat (one) and neis (two). Higher numbers would be described either by reduplication, as neis netat, literally, two-one for three; neis-i-neis, or two-two for four, &c., or by reference to some part of the body. By the latter method a total of thirty-one could be counted. The counting commenced at the little finger of the left hand, thence counting the digits, wrist, elbow, armpit, shoulder, hollow above the clavicle, thorax, and thence in reverse order down the right arm, ending with little finger of right hand. This gives twenty-one. The toes are then resorted to, and these give ten more. Beyond this number the term gaire (many) would be used. English numerals are now in general use in the Islands.

The Chinch Bug (*Blissus leucopterus*, Say), one of the most destructive of North American insects, forms the subject of *Bulletin* No. 15 (New Series) of the U.S. Department of Agriculture, Division of Entomology. A previous report on the same subject, by Dr. L. O. Howard, was published as No. 17 of the Old Series of the *Bulletin*: the present has been prepared and brought up to date by Prof. F. M. Webster, the entomologist of the Ohio Agricultural Experiment Station, under Dr. Howard's supervision. The Report deals with the probable origin, diffusion and habits of the insect, with notices of the natural checks to its increase, and the remedial and preventive measures which may be used against it. The Report also includes a notice of various American *Hemiptera* which are likely to be mistaken for the Chinch Bug; and of an allied species (*Blissus doriae*, Ferr.) which occcurs in Italy and Hungary.

Dr. G. Christian Hoffmann sends a report of the Section of Chemistry and Mineralogy of the Geological Survey of Canada. Aided by two assistants, Mr. F. G. Wait and Mr.

R. A. A. Johnston, analyses have been made of coals and lignites, of various minerals, ores, rocks, and waters. Among the minerals, there is one named Baddeckite, a new variety of Muscovite, found at Baddeck, Victoria Co., Nova Scotia. It is a hydro-muscovite, in which a very large proportion of the alumina is replaced by ferric oxide. The occurrence in Canada of Chalcanthite and Xenotime are for the first time recorded. An analysis of a spring-water on Cañon Creek, in Alaska, proved the presence of 266 grains of mineral matter—chiefly salts of lime and magnesia.

THE Devonian fossils of Canada have for many years been a subject of special study by Mr. J. F. Whiteaves, palæontologist to the Geological Survey of Canada. In the concluding part of the first volume of "Contributions to Canadian Palæontology," Mr. Whiteaves describes some additional or imperfectly understood fossils from the Hamilton formation of Ontario. These include some supposed Cliona-borings, Corals, Crinoids, Polyzoa, Mollusca, Crustacea and Fishes. Mr. Whiteaves adds a revised list of all the known fossils from the Hamilton formation. Of these, *Atrypa reticularis* appears to be the only well-known European species. The Fishes include *Ptyctodus* and *Aspidichthys*.

MR. JOHN H. SCHAFFNER, of the Ohio State University, writing in the *Journal of Applied Microscopy*, recommends the use of anilin safranin and gentian violet as affording a very good and durable stain for starch grains.

FROM Prof. Jamshedji Edalji we have received papers on "Reciprocal Polygons" and "Associated Conics," in which many well-known theorems and other less-known properties of conics are proved, the method of reciprocation being largely used. The properties of ellipses touching a pair of conjugate hyperbolas afford interesting exercises, but we could wish that the text and figures were rather better printed.

MESSRS. G. W. BACON AND CO., LTD., have just published a well-coloured wall diagram of common poisonous plants. The pictures of the foxglove, woody nightshade, and monkshood are particularly good. The chart should be very useful in country schools to familiarise children with the plants to be avoided.

PROF. MANDEL'S translation of Prof. Hammarsten's "Text-book of Physiological Chemistry" was reviewed in these columns four years ago (vol. l. p. 449). A second American edition, prepared from the third revised German edition by the same translator, who produced an excellent English version of the earlier one, has now been published by Messrs. John Wiley and Sons. The new volume is essentially the same as the first edition, being simply brought up to date.

A COPY of the first number of *Science Work*—a monthly review of scientific literature—has been received. The contents consist of a few general notes, the titles of a selection of articles which have recently appeared in some periodicals, a directory of lecturers, and a synopsis of some scientific expeditions now in the field. The publishers of this venture are Messrs. Robert Aikman and Co., Manchester.

WE have received a copy of a pamphlet entitled "Replica di Krupp alla Protesta del Signor Bashford," published by the Cambridge University Press. In the *Revista di Artiglierca e Genio*, Dr. Bashforth charged the Krupp firm with making use of his general tables of velocity and time, and velocity and space, containing the results of his experiments, without acknowledgment. Mr. F. Krupp has replied on behalf of the firm, and the pamphlet now received contains a translation of this letter presenting the Krupp view of the matter, with an introduction and notes by Dr. Bashforth, which he holds afford ample justification for his protest.

THE last two parts received (Heft 3 and 4) of Engler's *Botanische Jahrbücher fur Systematik, Pflanzengeschichte, u. Pflanzengeographie* contain the following articles:—The conclusion of Hieronymus's account of the Pteridophyta of Argentina; Anderson on the History of the Vegetation of Sweden; Höck on the Flora of the alder-plantations of North Germany; Fedtsckenko on the Flora of the southern Altai mountains; a continuation of Pfitzer's Classification of the Orchideæ; the commencement of a paper by Perkins on the Monimiaceæ; and a description by Hallier of *Hildebrandtia*, a new diœcious genus of Convolvulaceæ.

THE number of new syntheses capable of being carried out with the aid of diazomethane, would appear to be by no means exhausted. Prof. H. von Pechmann describes in the current number of the *Berichte* a new synthesis of pyrazol by means of this active reagent. A solution of diazomethane in ether is cooled to 0° C. and saturated with dry acetylene in a large flask, and the whole allowed to stand. The reaction is rather slow, about two days being required; simple evaporation then deposits pure pyrazol in fine prisms in quantity about fifty per cent. of the theoretical value.

THE announcement is made (by M. and Mme. Curie and M. Bémont), in the current number of the *Comptes rendus*, of the probable existence of a new element, to which the name of radium is provisionally given. It will be remembered that M. Becquerel discovered that the metal uranium and its salts possessed the remarkable property of emitting rays much resembling the X-rays in penetrative power and action upon electrified gases. Using this new weapon of research, M. and Mme. Curie were able to isolate from pitchblende a new element (*polonium*) resembling zinc in its chemical properties, differing from this metal, however, in possessing radio-active properties of a similar character to uranium, but of greater intensity. In following up this work they (in conjunction with M. Bémont) have now obtained indications of another element possessing still more powerful radio-active properties, and chemically resembling barium, inasmuch as it is precipitated neither by sulphuretted hydrogen, by ammonium sulphide, nor by ammonia; the sulphate is insoluble in water and in acids; the carbonate insoluble in water; and the chloride, although very soluble in water, insoluble in alcohol. Fractional precipitation of the chlorides by alcohol showed an increasing amount of radium in the precipitate, as measured by its radio-activity, the final fractions possessing an activity 900 times greater than uranium. The spectrum of this chloride was found by M. Demarcay to give, besides the lines of barium, lead, calcium and platinum, a strong new line ($\lambda = 3814{\cdot}8$), which in his opinion confirms the existence of a new element.

IN a recent number of the *Proceedings* of the American Academy of Arts and Sciences, Prof. T. W. Richards, of Harvard, describes a series of interesting experiments on the retention and release of gases occluded by the oxides of metals, a subject of special importance to those engaged in the determination of atomic weights. He shows that oxide of copper prepared by ignition of the nitrate contains between four and five times its volume of occluded gases up to a temperature of 860° C. Slightly above this temperature the bulk of the gas is given off, but before 1000 is reached the copper oxide itself decomposes. Of the gases resulting from the decomposition of the nitrate, the oxygen escapes more rapidly than the nitrogen. The explanation given by Prof. Richards is that the gases proceed from basic nitrate imprisoned in the oxide, the N_2O_5 being resolved into nitrogen and oxygen. The oxygen escapes more rapidly than the nitrogen, by uniting with metal or a lower oxide which has momentarily released some of its proper supply of oxygen. The released oxygen passes onwards and

outwards by a similar process, so that there is a continuous transference of oxygen by a sort of Grotthus chain of unstable copper oxide molecules. This view is in harmony with the fact that cupric oxide, the most easily reducible of the oxides investigated, is the one which parts with its occluded oxygen most easily, at the same time obstinately retaining the nitrogen, whilst the oxides of zinc and magnesium, being more stable, retain the oxygen persistently. It was found that the electrical conductivity of copper oxide was much increased at a temperature approaching redness, whilst that of zinc oxide was much less increased, and that of magnesium oxide not at all. This would be explained by the copper oxide being to a certain extent dissociated by heat, and permitting of some metallic conduction. Cupric oxide was found to give up oxygen steadily when heated in vacuo to 790°, cuprous oxide being found in the residue.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. A. Urban Smith; six Snow Buntings (*Plectrophanax nivalis*), European, purchased; three Grey Squirrels (*Sciurus cinereus*) from North America, deposited; a Great Eagle Owl (*Bubo maximus*), bred in the Gardens.

Errata.—In the necrology of Prof. Allman, p. 202, line 18, delete "Regius"; p. 204, line 37, for "Grumera" read "Gunnera."

OUR ASTRONOMICAL COLUMN.

COMET CHASE.—The following ephemeris of Comet Chase is a continuation of that which we have previously published from Herr J. Möller's computation:—

1899.	R.A. (app.) h. m. s.	Decl (app.) ° ′	Br.
Jan. 1	11 5 50	+29 23·5	1
7	6 45	29 46·1	1
9	7 33	30 8·7	1
11	8 14	30 31·5	1
13	8 48	30 54·6	1
15	11 9 15	+31 17·9	1

PLANET WITT (DQ 1898).—Although only of the twelfth magnitude, planet Witt should be closely followed and good positions measured as opportunities afford. The accompanying ephemeris for the coming fortnight will prove useful to those whose instruments are large enough to follow this interesting body.

Berlin Midnight.

1898.	R.A. h. m. s.	Dec. ° ′
Jan. 5	23 3 0	+4 37·6
7	7 51	5 3·3
9	12 45	5 29·6
11	17 42	5 56·1
13	22 44	6 23·0
15	27 48	6 50·2
17	32 56	7 17·7
19	23 38 6	+7 45·4

The above ephemeris, calculated by Dr. E. Millosevich (*Astr. Nachr.*, 3532), requires, according to an observation by Dr. Cerulli, a correction of about - 5s. in R A., and - 0′·3 in declination.

ASTRONOMICAL PHOTOGRAPHY WITH SMALL INSTRUMENTS.—The earnest worker, even with only small means at his disposal, may perform important work in astronomy by the aid of lenses of comparatively small aperture. The great advances made in the sensitiveness of dry plates helps us now to photograph quite easily objects which formerly presented a great difficulty.

By replacing the eyepiece of a good telescope with a small camera, with a suitable positive or negative lens, very useful work can be done, although the scale of magnification need not be very great. The employment of a negative lens makes the instrument more convenient for use, as a shorter telescope tube can be utilised.

One great function of photographs of celestial objects is to record changes in the appearance of bodies or regions studied. In the case of the former large images are required, and the photo-telescopes are the most suitable; in the latter, large fields, but not necessarily very large magnification, are required for many purposes of great interest. In the *Photographische Correspondenz*, Herr P. Zschokke points out in an interesting article the useful work an amateur can accomplish by means of small instruments, and gives an interesting table showing the relative sizes of apertures, focal lengths of objectives, focal lengths of combinations, &c. Since, in this class of instrument, the size of the diameter of the image formed is the main point, we give below the table containing these values, which has been reproduced in the *British Journal of Photography* (December 23, 1898). All the figures in the following columns refer to millimetres.

Aperture.	Focus of objective.	Focus of tele-photo combination.	Entire length of telescope.	Diameter of image of sun or moon.
61	730	5370	980	50
81	1218	8060	1350	75
108	1624	11370	1960	108
135	1949	16115	2365	150
135	1353	16115	1800	150
162	2599	32230	3510	300
162	2599	24170	3155	225

A NEW VARIABLE IN CASSIOPEIA.—Dr. T. D. Anderson, writing in the *Astr. Nachr.* (No. 3533), states that the star which has the position for 1855, R.A. 23h. 37·5m., and Decl. + 55° 45′, is a hitherto unnoticed variable. This star, which is not recorded in the BD, was first seen by Dr. Anderson in the beginning of 1897, and was then only 0·2 magnitudes fainter than + 55°·3007, the magnitude of which was then fairly estimated as 9·0. In September 23 of the same year the star was found missing, although another star of magnitude 10·3 could be easily seen 3′ to the north of the missing star. Subsequent searches failed to pick up the same star again; and Dr. Anderson, coming to the conclusion that the object was probably a Nova, only examined the region very occasionally.

Last month, however, on the 5th, he again examined the region, and at last found the object of his search. At this time it excelled in brilliancy its neighbour of magnitude 10·3 by as much as it was itself surpassed by BD + 55°·3007.

OBSERVATIONS OF α ORIONIS.—Mr. R. T. A. Innes, writing from the Cape Observatory (*Astr. Nachr.*, 3533), mentions that he has been observing α Orionis (Betelgeuze) on several evenings, and the star was found to be only slightly brighter than Aldebaran. Last season, as Mr. Innes states, Betelgeuze was twice as bright as Aldebaran, which is its ordinary state. From this observation it may be concluded that one of the irregular minima of Betelgeuze is approaching.

PRIZES PROPOSED BY THE PARIS ACADEMY OF SCIENCES FOR 1899.

THE following are the prize subjects proposed by the French Academy of Sciences for the present year.

The Bordin Prize (3000 fr.) for a study of the questions relating to the determination, properties, and application of systems of orthogonal curvilinear coordinates of n variables, indicating particularly, in as precise a manner as possible, the degree of generality of these systems; the Francœur Prize (1000 fr.) and the Poncelet Prize (2000 fr.), for useful work in the field of pure and applied mathematics. In Mechanics is offered the Extraordinary Prize of 6000 francs, for any invention increasing the efficiency of the French naval forces; the Montyon Prize (700 fr.), for the invention or improvement of instruments useful to the progress of agriculture or the mechanical arts; the Plumey Prize (2500 fr.), for any invention contributing to the progress of steam navigation; the Tourneyron Prize, for an improvement in any point of the theory of pumps. In Astronomy, the Lalande Prize (540 fr.), for the most interesting or useful astronomical observation made during the year: the Valz Prize (460 fr.) for astrononomical work. In Physics, the La Caze Prize (10,000 fr.). In Statistics, the Montyon Prize (500 fr.). In Chemistry, the Jecker Prize (10,000 fr.) for discoveries in organic chemistry; the Cahours Prize (3000 fr.) for the encouragement of research in young chemists already known by their published work; and a La Caze Prize of 10,000 fr. In Mineralogy and Geology, the Delesse Prize (1400 fr.), and the

Fontannes Prize (2000 fr.) for researches in palæontology. In Biology, the *Grand Prix* of the Physical Sciences (3000 fr.) for a study of the biology of Nematods, especially the forms and conditions of their reproduction, and the Bordin Prize (3000 fr.). In Botany, the Desmazières Prize (1600 fr.) for work on the Cryptogams; the Montagne Prizes (1000 fr. and 500 fr.) for important work bearing on the anatomy, physiology, development, or description of the lower Cryptogams; and the Thore Prize (200 fr.) for the best memoir on the cellular Cryptogams of Europe. In Anatomy and Zoology, the Savigny Prize (975 fr.) for the assistance of young travelling zoologists. In Medicine and Surgery, a Montyon Prize for discoveries or inventions having a direct bearing upon the art of healing; the Barbier Prize (2000 fr.) for similar objects; the Bréant Prize (100,000 fr.) for the discovery of an absolute specific against Asiatic cholera; the Godard Prize (1000 fr.) for the best memoir on the anatomy, physiology, and pathology of the genito-urinary organs; the Serres Prize for a memoir on general embryology applied as far as possible to Physiology and Medicine; the Chaussier Prize (10,000 fr.) for the best book or memoir which has appeared during the last four years, either in medicine, legal or practical medicine; the Bellion Prize (1400 fr.); the Mège Prize (300 fr.); the Lallemand Prize (1800 fr.) for work on the nervous system; and the Baron Larrey Prize (1000 fr.) for a memoir on military or naval medicine, surgery, or hygiene. In Physiology, a Montyon Prize (750 fr.); a La Caze Prize (10,000 fr.); the Pourat Prize (1400 fr.) for a memoir on the specific characters of the contraction of different muscles; and the Philipeaux Prize (890 fr.) for work in experimental physiology. In Physical Geography, the Gay Prize (2500 fr.) for a study of the Mediterranean mollusca, and a comparison of these with those found on the French oceanic coasts.

Other general prizes offered for 1899 include the Arago Medal, the Montyon Prize (unhealthy trades), the Trémont Prize (1100 fr.), the Gegner Prize (4000 fr.), the Petit D'Ormoy Prizes (10,000 fr. each), one for work done in mathematics, and the other in natural science; the Leconte Prize (50,000 fr.), the Tchihatchef Prize (3000 fr.), the Gaston Planté Prize (3000 fr.), the Houllevigue Prize (500 fr.), the Wilde Prize (4000 fr.), the Saintour Prize (3000 fr.), the Kastner-Boursault Prize (2000 fr.), the Jean-Jacques Berger Prize (12,000 fr.), and the Baron Joest Prize (2000 fr.).

Of these the prizes bearing the names of Wilde, Tchihatchef, Leconte, Desmazières, Delesse, La Caze, and Lalande are expressly stated to be offered without distinction of nationality.

MAGNETIC SURVEYS.[1]

THE importance of magnetic survey work has been recognised for a long time. Many of the most eminent scientific men of the century now about to close have devoted much time and thought to magnetic observation and the reduction of results, and their labours have not been without fruit. To them we owe all that is known with certainty as to the magnetic state of the earth and its changes; and though observations have no doubt to some degree outpaced the work of reduction and the construction of theory, much has been done to construct from observational data a general theory of terrestrial magnetism. We have the great mathematical theory of Gauss based on the results of Sabine, Barlow, Horner, and others, with the answer it gives to the question of the locality of the magnetic distribution which gives rise to the ordinary phenomena of terrestrial magnetism. Also, and founded to some extent on Gauss's theory, we have now that of Schuster on the daily changes of the magnetic forces and their causes, which has yielded most important results, as to the locality of the sources of this periodic disturbance. As a consequence of Schuster's theory there have lately been published some important discussions of the diurnal changes and their theory by von Bezold and others.

The secular changes have received a great accession of interest since Bauer's first discussion of the subject some years ago in an inaugural dissertation at the University of Berlin. In that he gave the method of graphical representation of the secular changes now known by his name. An observer is supposed to look from the centre of a magnet, freely suspended at its centre of gravity, and to note the curve which the north-pointing pole seems to describe, and which shows changes of dip as well as changes of magnetic declination. This mode of representation can, of course, be applied to the diurnal changes, and shows that though a complete cycle of secular changes is not yet available from observations, yet the diagram of the diurnal changes may serve to complete it. Let the secular changes be produced by the combination with a constant magnetic system rotating with the earth of a second system, also turning with the earth, but while doing so describing a secular orbit round the earth's axis. This is the hypothesis of Wilde. Now let a needle be imagined suspended outside the earth while the earth turns beneath it. The superimposed magnetic system will in the course of one rotation of the earth occupy the same position relatively to the suspended needle that it successively occupies in the secular period with reference to a needle fixed with the earth and turning with it. The curve thus obtained for a single day will, if the second system be invariable and its successive positions be symmetrical about the earth's axis, be the same as the secular curve. Though this curve cannot be directly observed, for no needle can be suspended in the manner supposed, the distribution of magnetic force round the earth is sufficiently well known to enable the positions of the needle to be calculated and the curve laid down on paper. The indications at the same instant of time of needles suspended at different points of the same astronomical circle of latitude, in fact, give the curve. There is sufficient similarity between the curves obtained in this way[1] to afford a fairly satisfactory first test of Wilde's hypothesis, and no doubt further progress in the solution of this interesting question will shortly be obtained by Dr. Bauer himself, or others.

The origin of the diurnal and secular variations may perhaps become known fully only when the secret of terrestrial magnetism itself is revealed. In the meantime there can be no question of the absorbing interest of the problem, and of the fact that the only way to solve it is by means of continued magnetic observation at different parts of the world, at sufficiently equipped and properly chosen magnetic observatories. It is to be hoped that as the value of observations, so far as the secular changes are concerned, depends on their comparison with those obtained much later in time, care will be taken in future by municipal and government authorities not to injure or render nugatory the work done by bringing disturbing electric currents and traffic into the vicinity of observatories. The fact that a sub-section (of Section A) of the British Association gave itself at the recent meeting to the discussion of terrestrial magnetic problems is at once an indication of fuller recognition of the interesting nature and the importance of magnetic research, and a guarantee that magnetic observatories and laboratories will be made to co-operate to the best advantage in the work to be done, and that everything will be done to induce authorities to protect them when powers are being sought for engineering projects.

Dr. Bauer has set before us a brief but interesting statement of the history of magnetic research, the objects to be served by it, the kind of survey work that may be attempted best by observers in different localities, and the mode in which it should be carried out, illustrated by an account of a survey of part of the State of Maryland which he has lately undertaken.

There are many notes of great interest in this historical sketch. For example we find, what we confess we did not know before, that the discoverer of the declination of the compass needle from the true north was Christopher Columbus. It seems that on September 13, 1492, Columbus crossed the agonic line, the line of no declination, a little to the west of the Island of Fayal in the Azores, and observed that the compass at places on the east of this line pointed east, and at places on the west pointed west of the true north. This line ran, curiously enough, along the old boundary between the kingdoms of Portugal and Castile. Generally Columbus has received credit only for discovering the agonic line, owing to a statement of Formaleoni, the Italian historian, that Bianco's chart of 1436 contained values of the declination, an error which Humboldt perpetuated by repeating in his "Cosmos." The recorded value of the magnetic declination at Rome in 1269, ascribed to Petrus Peregrinus, was inserted, it appears, by some one early in the sixteenth century, thus subsequent to Columbus.

That the declination had not been discovered sooner arose

[1] "Maryland Geological Survey: First Report upon Magnetic Work in Maryland, including the History and Objects of Magnetic Surveys." By L. A. Bauer. Special Publication, Vol. I., Part V. Pp. v + 125, with one plate. (Baltimore: The Johns Hopkins Press, 1897.)

[1] See Prof. Rücker's Rede Lecture, NATURE, December 23, 1897.

from the fact that it was but small over the greater part of the Mediterranean, and so for long the deep-sea sailors of Europe were without much experience of its effects. When it did force itself on their notice it was supposed to be due to an error of construction, and a correction was made so that the point marked north on the card pointed to the astronomical north.

The importance of Gilbert's "De Magnete" has only been fully seen in the light of modern magnetic research. It constituted in itself an advance which has not been equalled by any single step during the three hundred years that have elapsed since its publication. So far as observation and theory have yet gone, even with the aid of Gauss's refined analysis, they have only confirmed the conclusion there set forth, *Magnus magnes ipse est globus terrestris*—"the earth is a great magnet." It is of great importance to decide whether or not the earth is a permanent magnet like a piece of steel, but the decision that its magnetism is induced by currents of electricity will not in any way contradict Gilbert's assertion.

Magnetic survey work has of course its own practical and commercial importance, but in a country like America, where public and private boundaries have been laid down by the compass, the determination of the secular variation is of peculiar interest. Without it the results of early land surveys could not now be interpreted.

In all cases the earlier surveys in America were compass surveys, and the directions referred to the magnetic meridian. Hence, as the deviation of the magnetic from the true meridian was known only in a few cases, the directions laid down in old topographical maps and plans of estates can only be recovered by determining the deviations now, and applying the known value of the secular variation. And Dr. Bauer says that one of the Eastern states actually still retains the magnetic meridian as the legal meridian of reference for land surveys. We had thought that such conservatism was unknown on the other side of the Atlantic.

Dr. Bauer quotes Robert Norman's own account of his discovery of the dip.[1] It has been quoted before, but not many have seen it, so we venture here to make a short extract. After stating that he had repeatedly found needles which had been finished and balanced before magnetisation inclining themselves to the horizontal with the north pole down when magnetised by being stroked with a lodestone, so that he had to "put some small piece of wire on the south point, and make it equall againe," but had put the result down to defect of construction rather than to "anie such propertie in the stone," he goes on: "It chaunced at length that there came to my hands an instrument to be made with a needle of sixe inches long, which needle after I had polished, cut of a just length, and made it stand levell upon a pin, so that nothing rested but onlie the touching it with the stone; when I had touched the same, presentlie the north part thereof declined down in such sort that being constrained to cut awaie some of that part to make it equall againe, in the end I cut it too short, and so spoiled the needle wherein I had taken so much paines. Hereby being stroken into some cholar, I applied myself to seeke further into this effect. . . ."

The first systematic surveys were made by William Whiston, better known perhaps as the translator of "Josephus." He was active in carrying on magnetic observations with a view to the determination magnetically of geographical position, and first drew isoclinics, made relative intensity observations, and invented the vibration method of obtaining the dip. His main object was to obtain the prize offered for the best solution of the problem of determining the longitude at sea, and he seems to have been successful in enlisting the interest of the Court, and even in obtaining money grants in aid of his work. Although the problem of the longitude was to be quite otherwise solved, Whiston's researches were of very great value. From Whiston to Gauss is a hundred years, but the next great development in terrestrial magnetic science came when Gauss introduced absolute measurement, and thus led observers to express results in units independent of arbitrary constants, so that they were at once available as data for other investigators. As a result the science has gone on vigorously from then till now developing in interest and importance. This, of course, is only one part of the effect of Gauss's work: it has been equally, if not more, productive of progress in the science of pure and applied electricity.

With respect to the conduct of magnetic survey work generally, Dr. Bauer makes some remarks which it would be well if observers would bear in mind. Much time and labour has been practically lost by the observation of only a single element, such as the declination. As he says, fully 75 per cent. of the time and money spent on a survey is spent in *occupying* stations, and the remainder only in observation. Thus it is only a very little further expense comparatively for an observer to observe a little longer, and get with sufficient accuracy values of all three elements. Thus magnetic declination surveys are of little value by themselves, except for the land surveying application, and those which have been carried out in many places could have been rendered many times more valuable to science by a very trifling additional outlay.

The initiation of terrestrial magnetic work by the British Association, the magnetic surveys carried out in this country by the British Association, and described in Sir Edward Sabine's Report for 1861, the more recent elaborate surveys by Thorpe and Rücker, and the work done in other parts of the world, are all appreciatively referred to.

Now that the British Association has again taken up the work in a very special manner, and a magnetic committee has been appointed, we may confidently expect to see a further great development of the subject. The work done by the conference at Bristol, under the presidency of Prof. Rücker, is a valuable instalment.

A. GRAY.

PROGRESSIVE EDUCATION.[1]

THE publication of the second and third volumes of the series of reports prepared for the Education Department under the supervision of Mr. Michael E. Sadler, the Director of Special Inquiries, again calls the attention of educationists to the value of the work which is being performed by this latest addition to our national machinery for the guidance and coordination of educational effort. These reports, with their predecessors, closely resemble in their scope the publications of the U.S. Bureau of Education, and accentuate the fact that we have only lately commenced to do what has been for some time the established custom in the States. Just as the man of science acquaints himself with the work, failures and successes alike, of previous investigators in the field of his own activity, so to do the best possible work, the teacher, who is also an experimenter, should similarly become familiar with what has been accomplished by other teachers in different parts of the world. With these reports to hand, and others which will doubtless follow, there is no reason why the schoolmaster should not, in the future, start the education of his pupils armed with the experience of many successful veterans.

Though every one of the 1389 pages included in these volumes contains something of interest, this article is to be concerned more especially with what there is to be learnt concerning the present state of the teaching of science—whether in this country or abroad. Of the many plans of treatment which suggest themselves, perhaps, as reference to the volumes will be thereby facilitated, it will be best to take the papers containing important allusions to scientific instruction in the order in which they occur in the volumes themselves.

THE LONDON POLYTECHNIC INSTITUTES.

The London Polytechnic has but little resemblance to the institutions to which a similar name is applied in France, Switzerland, and Germany. Each Polytechnic Institute (of which there are at present eleven, with four branches) is an independent organisation which deliberately combines social intercourse, recreation, and instruction. As educational institutions these polytechnics constitute a new and distinct type; they range from the "Upper Standard" day school for boys and girls of thirteen, up to high University instruction and post-graduate research. All kinds and grades of work go on simultaneously. In one room boys of twelve are learning arithmetic, or girls of thirteen are being taught to sew; in another, classes of plumbers or bricklayers, compositors or tailors, are being practically trained in the processes of their respective crafts; close by is the smithy or the fitting shop, crowded with young engineering artisans; in other class-rooms are groups reading Dante or studying economics; and just at hand are well-equipped physical and chemical laboratories where

[1] "Special Reports on Educational Subjects." Vols. ii. and iii. (Issued by the Education Department, 1898.)

(as at Battersea this year) the teacher with a selected band of students is working out a Royal Society grant for research, or (as at Chelsea) graduates of more than one University are preparing their theses for the doctor's degree.

Six of the polytechnics now possess day schools and these have together about 1600 pupils, who are chiefly between twelve and fifteen years of age. Two of them are mixed schools for boys and girls, one has separate departments for the sexes, and three are confined to boys. They are in the main to be regarded as technical continuation schools. Seven day schools of a special type—the Domestic Economy School—are also attached to various polytechnics. In these the whole time of the pupil is spent in the study and practice of cookery, dressmaking, plain needlework, laundry work, and housewifery, with some elementary lessons in the chemistry of food and the physiology of hygiene. At Chelsea there is also a training school for servants.

At least 5000 workmen are at present attending the trade classes in connection with the London polytechnics. Not only is there a class in each branch of the building, engineering and metal, furniture, book and printing, and clothing trades, but also in such miscellaneous trades as baking, basket-making, and gas manufacture.

One polytechnic after another has found itself pushed into providing day instruction of various kinds, by the demand of students for whom evening classes are inaccessible or unnecessary. Thus the Battersea Polytechnic has regular day courses in mathematics and science, building and machine construction, wood-work and metal-work. The East London Technical College and the Regent Street Polytechnic have each a regular day engineering department, which turns out fully equipped engineers and electricians. At Regent Street a day architectural school has just been added. The Birkbeck Institution has a rapidly growing day department in natural science, including systematic courses in physics, chemistry, and biology. There are also day classes in Latin, Greek, and French, up to the standard of the B.A. degree of London University. At Chelsea there is a fully developed Technical Day College for men and another for women.

More than one provincial city, proud of its "University College," counts fewer systematic day students than a single London Polytechnic.

In the science laboratories of the polytechnics every attempt is made to render the instruction both practical and scientific, and in addition to the crowds of elementary pupils there is generally a small body of enthusiastic advanced students who spend every hour they can spare in the laboratory, carrying on original research under the personal direction of the lecturers and demonstrators. This is sometimes systematised into what, in a German University, would be called a "Seminar." The research course at the Chelsea Polytechnic, under the direction of Mr. Herbert Tomlinson, F.R.S., may be cited.

The subject selected for the first research is "The effect of repeated heating on the magnetic permeability and electrical conductivity of iron and steel." The investigations are being accompanied by demonstrations and lectures on (1) the best methods of annealing iron and steel and the faults incidental thereto; (2) the determination of magnetic permeability both by ballistic and magnetometric methods; (3) the determination of the electrical conductivity of magnetic metals; (4) the critical temperature of iron and its alloys.

The method of conducting the research is, too, worthy of mention. To begin with, the principal selects some suitable subject, and fully explains to the class his reasons for such selection. He then gives a brief history of what has been previously done round and about the subject, and propounds a mode or modes of attacking the research, inviting criticisms from the class. The mode of attack having been decided upon, the class is expected not only to take part in the experiments but to help in making necessary apparatus. Should the results obtained be of sufficient importance, they are to be offered in the form of a paper to such societies as the Royal Society, the Physical Society, or the Institution of Electrical Engineers.

Enough has been culled from Mr. Sidney Webb's paper to show that the London Polytechnic is a pure addition to the educational system, neither competing with nor superseding existing institutions. There are, among all the 50,000 members and students of these new establishments, probably not a dozen who would have been found joining University or King's College had the polytechnics never come into existence. There is, Mr. Webb says, every indication that the whole 50,000 are a net gain, and represent the arrival of a poorer class of students than the University Colleges have as yet reached.

Science in Girls' Schools.

Mrs. Bryant, headmistress of the North London Collegiate School for Girls, in a paper on "The curriculum of a girls' school," while admitting that the scientific interest arises almost as early in a child's mind as the literary and human interests, lays it down that the power to satisfy it develops much more slowly, so that the progress made is comparatively insignificant, even when the time spent is considerable and the methods sound. Nevertheless, it is recognised that the youngest children of school age are capable of elementary work in natural history. Such work at the beginning can hardly be called natural science, but it is of the nature of science if rightly carried out. An hour a week, increasing to two hours, may thus be profitably spent. At eleven or twelve children enter on physical science by very simple experimental investigations of the properties of matter. The ideal of the school curriculum in physical science is, it is suggested, a course of general elementary physics, starting with easy measurements and leading up to chemical problems, and eventually to chemistry. Mrs. Bryant thinks it is better for girls to carry on chemistry as a special study than to pursue any of the physical branches to the same extent. It has been found that backward pupils, and those who enter school late, get their best chance of science by the pursuit of botany and natural history as regular studies, with occasional courses on quasi-scientific subjects, like hygiene. All the pupils should, at some period of their course, deal with the application of science to life in some form, hence, short series of lessons, during one term, on hygiene and domestic economy, should be arranged. An interesting note by Miss Edith Aitkin, the science mistress in the school of which Mrs. Bryant is headmistress, gives in detail how the science teaching in the North London Collegiate School for Girls is carried out.

The Heuristic Method of Teaching.

The art of making children discover things for themselves is the meaning Prof. Armstrong applies to the expression Heuristic method of teaching, and he contributes a very suggestive article on this theme to the second volume of the reports. After what is best described as an autobiographical account of his gradually developed belief in this system, Prof. Armstrong sketches historically the work of the British Association Committee and the Incorporated Association of Head Masters in formulating a scientific and logical introduction to physical and chemical studies. In 1888 the British Association Committee reported at the Bath meeting, that the replies received to a letter addressed to the headmasters of schools in which chemistry was taught—"have put them in possession of the actual facts connected with the teaching of chemistry in schools, and have made it clear that something should be done in the direction of promoting a more uniform and satisfactory treatment of the subject. The Committee think that some suggestions might now be made as to the method of teaching chemistry which should be followed in schools. If this can be done, it will certainly confer a great benefit on both teachers and examiners, and will be likely to lead to a more emphatic recognition of the merits of the science as an instrument of elementary education."

Two years later the same Committee recorded that—"it cannot be too strongly insisted that elementary physical science should be taught from the first as a branch of mental education, and not mainly as useful knowledge. It is a subject which, when taught with this object in view, is capable of developing mental qualities that are not aroused, and indeed are frequently deadened, by the exhaustive study of languages, history, and mathematics. In order that the study of physical science may effect this mental education, it is necessary that it should be employed to illustrate the scientific method in investigating nature, by means of observation, experiment and reasoning with the aid of hypothesis; the learners should be put into the attitude of discoverers, and should themselves be made to perform many of the experiments."

In 1895 a committee, appointed by the Incorporated Association of Headmasters, prepared a detailed syllabus of instruction in elementary physics and chemistry on the lines sketched out by the British Association Committee, and this syllabus was adopted by the headmasters in 1896. This detailed schedule has had a marked effect, both upon the personal teaching in

secondary schools, and also upon the character of the text-books which have been published from time to time for use in such schools.

Not only have many headmasters been won over to this newer and more intelligent mode of imparting scientific instruction, but the various examining bodies—the local examination authorities at Oxford and Cambridge, as well as the Senate of the London University—are all moving in the same direction. Examinations in elementary experimental science are becoming more and more practical. It is yearly becoming less common for examiners to be satisfied with verbal descriptions of scientific experiments, the candidates must be able to perform the experiments themselves and also draw the proper inferences from them.

In addition to other reasons why the heuristic method of teaching should be adopted, Prof. Armstrong claims for it that it conduces to the formation of moral and intellectual character and purpose. Children are encouraged to be properly inquisitive and inquiring; to observe correctly; to be neat and careful in all their work; to be economical; to attend patiently to details; to reason with judgment; to be handy, and to develop many other equally valuable characteristics.

For instruction in science to be carried out according to heuristic methods, ample room must be provided, but there need be no very special arrangements made. Prof. Armstrong enumerates the comparatively few necessaries in the way of fittings; they are: unfixed benches of the kitchen-table type, fitted with gas; one or two long sinks made of wood—elongated washing tubs; one or two benches fixed against the wall of the room, with cupboards (having a tray which will slide in and out) fixed in the space underneath; single draught-closet; considerable amount of wall space converted into blackboard; and free wall space, having upright battens affixed at regular intervals for attaching shelves or hooks. Apparatus should be provided to meet requirements as they arise, and "every effort should be made to utilise ordinary articles—medicine and pickle bottles, jam pots, saucepans, &c.—and to construct apparatus in the workroom; for this latter purpose a carpenter's bench and tools, vice and files, a small lathe, an anvil, and even a small forge should, whenever possible, form part of the equipment. Infinite injury is done at the present day, invaluable opportunities of imparting training are lost, by providing everything ready made." Centimetre-foot-rules, drawing-boards, T and set-squares, and balances *must*, however, be supplied. But the greatest of these is the balance. Says Prof. Armstrong, "altogether indispensable and essential as the primary weapon of heuristic instruction is the balance. There is no question that in the future the test of efficiency in a school will be the extent to which suitable balances are provided and used." Or, again, "the balance is to be regarded as an instrument of moral culture, to be treated with utmost care and reverence."

Appended to the article are the full courses of instruction in elementary science adopted by the Incorporated Association of Headmasters, and a course in botany framed by Prof. Marshall Ward, and included in the programme of the Joint Scholarships' Board Examinations.

PRUSSIAN SECONDARY EDUCATION FOR BOYS.

It is interesting to read, in the article entitled "Problems in Prussian Secondary Education for Boys," which Mr. Sadler contributes to vol. iii., of the part von Humboldt took in developing an effective plan of educational administration in Prussia. Humboldt was appointed Director of Public Education in 1792, and during the succeeding seventeen years was actively engaged in supplying the urgent need which was then felt for improved education. He insisted, among other things, that no one should be allowed to undertake higher education, even in private schools, who did not hold a certificate of competency awarded by a State authority. In 1808, he began to remodel Prussian secondary education; and the work of the succeeding ten years is carefully reviewed in Mr. Sadler's article. The eleventh section of this exhaustive inquiry is of especial importance at this time. It is concerned with the manner in which the growing need for more knowledge in the various branches of professional and commercial life has been met in Prussia. As Mr. Sadler says, "a really good secondary education, up to sixteen or nineteen as the case may be, does for a man what he can rarely do for himself in later years. It drills his intelligence, while the powers are still supple, and it presses into his mind, while the memory is still retentive and undisturbed by outside cares, a well-set foundation of necessary knowledge. But all over Germany these advantages have been made more accessible to the children of families of small means than is the case in England." It has been, moreover, a fixed principle in Prussia for some time, that the different types of secondary school should be kept distinct. "In the application of science to industry there has been an ever-increasing demand for young men of ability, well-trained in studies which equip them for business callings, instead of tending to estrange their sympathies from commercial life." The Education Department of Prussia now definitely accepts the idea of non-classical training as a part of a national system of higher education. The curricula and programmes of work for higher schools in Prussia, which follow the general article, should prove of great value in guiding English headmasters. That section which deals with natural science shows that in the gymnasium, or fully classical school, two hours a week are given in each form to the study of science. The teachers are instructed that "special importance is to be attached, not so much to the amount of what is learnt, as to the thoroughness with which it is studied." The endeavour must be "above all to guide the pupils to think and observe for themselves." In the Realgymnasium, or school with Latin only, and the Oberrealschule, or modern school, the amount of time given to science is increased in the higher forms to five hours a week in the Realgymnasium, and six hours a week in the Oberrealschule. It would take too much space to give a detailed account of the subjects, and the parts of them, studied in the different forms; but a reference to pp. 303–6 will give the necessary information.

HIGHER COMMERCIAL EDUCATION.

Mr. Sadler also contributes to vol. iii. an elaborate account of higher commercial education at Antwerp, Leipzig, Paris and Havre. The Institut Supérieur de Commerce at Antwerp aims at being a university for the future merchant, and at the special training of those to whom the consular service of the country will ultimately be entrusted. It is a public institution, under the inspection of the State, and its professors are civil servants. The Belgian government pays three-quarters of its annual cost, and the municipality of Antwerp the rest. Foreign students are admitted, and it is found that the associations thus formed are indirectly helpful to the furtherance of Belgian trade. The staff of the Institute consists of fourteen professors and two assistants, in addition to the director. To candidates who are successful in the final examination the Institute awards diplomas of merit, but these diplomas are not lightly given and are highly valued by business men. The diploma also qualifies a student to obtain one of the travelling scholarships awarded by the Government in order to encourage commercial inquiry. The scholarships are worth from 200*l.* to 250*l.* a year, and may be regarded as travelling studentships for commercial research.

One of the causes of the commercial advance of the German empire is the intellectual efficiency of the secondary schools, and of the higher Technical Institutes. "The secondary school is organised as the foundation, the higher Technical Institute as the crown." German non-classical secondary education prepares a boy to excel in commercial life, but the German secondary school authorities rigidly abstain on principle from any attempt at premature specialisation in commercial subjects. The first German Higher School of Commerce was last year established in Leipzig. There is to be a close correlation between this Higher School of Commerce and the University of Leipzig. The Director of the Leipzig School defines its objects "to be the raising of the position of the trading classes in social estimation, and their equipment with the higher level of expert knowledge which the conditions of modern industry require." Commercial opinion in Germany is not, however, unanimous in favour of the establishment of schools of commerce. Thus, in the Annual Report for 1897 of the Hamburg Chamber of Commerce the following remarks occur:—

"The science of business is a science which must be learned by practical experience. It cannot be picked up on the benches of a class-room. It must be acquired in practical life. A young man trained in a school of commerce will enter on practical life with his head full of all manner of preconceptions."

Mr. Sadler does not say much about the French Higher Schools of Commerce, but directs attention to the volume, "Commercial Instruction organised by the Paris Chamber of Commerce," which was prepared by that Chamber for the Chicago World's Fair of 1893. On the general question of commercial education, the following remarks are worthy of note. "All persons of experience heartily reprobate the

thrusting of so-called 'commercial subjects' into the curriculum of secondary day-schools. To cram up little boys of fifteen with odds and ends of commercial law and generalisations of commercial geography is to waste precious time which might have been devoted to subjects not only more elevating in themselves but more digestible by youthful minds."

CONCLUSION.

The foregoing sketch of some of the questions dealt with in the volumes under consideration does not exhaust the references to scientific instruction and higher education contained in them. Scattered through the reports are short allusions to other considerations which accentuate the importance of a fuller recognition of the claims of science as an effective instrument in education; and it is a happy augury that official publications of this kind should recognise so completely the good results which follow upon according science an important place in the curricula of secondary schools.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE annual meeting of the Association of Technical Institutions will take place on Thursday next, January 12, when an address will be delivered by the president, Lord Spencer.

THE canvassing committee under the Birmingham University scheme state that the total sum promised up to the date of the public meeting in the Council House in July last (95,658*l.*), had already been increased to about 115,000*l.* Mr. Frank McClean, F.R.S., has contributed the sum of 2000*l.* to the fund. The Lord Mayor of Birmingham announces a donation of 1000*l.* from Alderman T. S. Fallows, J.P. The committee will hold their next meeting on January 25, after which a second list of subscriptions will be published.

A WINTER meeting for teachers opened at the College of Preceptors on Monday, and will continue in session until the end of next week. The meeting was inaugurated by an address by Sir Joshua Fitch, and the programme also includes lectures on educational subjects, visits to educational institutions, a conference on the training of modern language teachers, a conference on science teaching, and a conversazione at the Clothworkers' Hall. The lectures will deal with the training of teachers, the practice of education (including the teaching of geography and of the "life sciences"), psychology applied to education, physiology applied to education, school hygiene, the training of the speaking voice, and other subjects. The conference on science teaching will be held at the South-West London Polytechnic, Manresa Road, Chelsea, next Thursday and Friday, and will consider the methods of teaching elementary experimental science (physics, chemistry and mechanics) in schools. In connection with the conference there will be an exhibition of apparatus used in schools for practical science teaching.

THE annual meeting of the Geographical Association will be held at the College of Preceptors on Wednesday, January 11, when an address will be given by the President, Mr. Douglas W. Freshfield. The Association was founded in 1893 with the object of improving the teaching of geography in secondary schools, and every one acquainted with what usually passes for geography instruction in such schools will acknowledge that there is much room for improvement. Rational methods of teaching experimental sciences are now being introduced into many schools, and geography ought to be brought into line with the new movement, for, when properly taught, it has a distinct educational value. All methods of science teaching which bring into play the pupil's intelligence, instead of merely loading the memory with names and isolated facts, should be encouraged; and as the work of the Association consists in spreading knowledge of improved methods of teaching geography, it deserves support. Intending members should communicate with Mr. J. S. Masterman, 55 Campden House Road, London, W.

A *Times* correspondent at Bombay reports that, on Saturday last, Lord Curzon received a deputation from the provisional committee of the proposed Imperial University, or Research Institute, to be established in India for the purpose of post-graduate instruction in the higher scientific and technical branches of learning. The petition referred to Mr. J. N. Tata's offer of property, representing a capital of 30 lakhs, and producing an income of a lakh and a quarter rupees, on trust to found an Imperial Institute, which it was thought would supply, with the help of the Government, the Native States, and the general public, this existing need. The present scheme was to found a separate institution open to graduates of all existing Universities, and fully equipped. The provisional committee submitted a draft Bill which had been prepared for the approval of the Government of India, with a scheme of studies and an estimate of the probable initial expenditure. The initial expenditure was put at 15 lakhs, and the annual charge at 3 lakhs. The committee asked for the support of the Government of India, as the proposed University was intended for all India, and, being Imperial in character, deserved special consideration from the supreme Government. The committee further requested the Government to sanction a grant in aid towards the annual expenditure, remarking that the Secretary of State for India would favour such a grant. If the Indian Government proposed to extend a grant in aid to higher studies, the native Princes would cordially co-operate. Some of them had contributed to the Jubilee Health Institute, ths object being bacteriological research, which fell within the confines of the committee's draft scheme. They suggested the amalgamation of the resources promised by the native Princes to the Jubilee Health Institute with Mr. Tata's donations, and pointed out that considerable funds had been raised in the Punjab and Haidarabad for research purposes. Lord Curzon, in reply to the deputation, said that he had carefully examined their representations, and, though he could, of course, give no final answer, he could, at all events, assure them that the object which they had in view had enlisted his warm sympathy.

PRESIDENT CRAFT's annual report of the Massachusetts Institute of Technology shows that the past year was a remarkable one in the financial history of the Institute. More money was received through bequests and gifts than in any previous year. Under the will of the late Hon Henry L. Pierce, seven hundred and fifty thousand dollars were paid to the Institute by his executors. This is the largest sum ever given to it by any one benefactor. In addition to this, the executors of the late Mrs. Julia B. H. James have paid over the very notable sum of one hundred and forty thousand and five hundred dollars, this being also one of the largest gifts ever made to the Institute. Mr. George A. Gardner has generously given twenty thousand dollars as a fund, the income from which is to be used in the payment of salaries. Ten thousand dollars came from the late John W. Carter, and fourteen hundred and eighty-two dollars has been added to the large sum previously received from the estate of the late Mrs. Susan E. Dorr for the Rogers Physical Laboratory. Besides these gifts to the Institute itself, a Travelling Fellowship in the Architectural Department has been established by the will of Mr. Willard B. Perkins. For this purpose the sum of six thousand dollars has been given, the accumulated income from which is to be used every fourth year. Forty thousand dollars came from the estate of the late Mrs. Ann White Dickinson, the whole sum for scholarship purposes. A friend has given five hundred dollars to meet a special want, and two hundred dollars has come from Mrs. William B. Rogers, to be used for periodicals. It is expected that the Institute will receive four hundred thousand dollars from the estate of the late Mr. Edward Austin. This amount appears to be intended for scholarships and other similar uses, and will be highly appreciated; but the great desideratum for the immediate future is accessions to the unrestricted funds of the Institute.

The actual expense of instructing the students at the Massachusetts Institute is on the average three hundred and thirty dollars per year, while only two hundred dollars is paid as tuition fees. The balance, one hundred and thirty dollars, including interest on permanent investments, land, buildings, machinery, &c., has to be met from the past and present government and private benefactions. All through the reports from the different departments of the Institute notices are given of the introduction of advanced studies in consequence of advanced entrance requirements, and the school is making continued progress towards a higher standard for its degree. Another noteworthy feature is the progress towards a greater subdivision of students into small sections in laboratories, and the constantly increasing value placed upon laboratory work. During the past four years this movement has led to the appointment of eighteen new instructors, while the total number of students has remained about the

same. The number of students last year was 1171. If any one figure can be taken as a measure of the efficiency of a well-conducted school, it is the ratio of the total number of students to the number of instructors in actual service. In the case of the Institute of Technology, without counting lecturers, there is one instructor to every eight or nine students—one of the very highest ratios in the United States.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 8, 1898.—"Mathematical Contributions to the Theory of Evolution. VI. Reproductive or Genetic Selection. Part I. Theoretical." By Karl Pearson. "Part II. On the Inheritance of Fertility in Man." By Karl Pearson and Alice Lee. "Part III. On the Inheritance of Fecundity in Thoroughbred Race-horses." By Karl Pearson, with the assistance of Leslie Bramley-Moore.

The object of this memoir is twofold: first, to develop the theory of reproductive or genetic selection[1] on the assumption that fertility and fecundity may be heritable characters; and, secondly, to demonstrate from two concrete examples that fertility and fecundity actually are inherited.

The problem of whether fertility is or is not inherited, is one of very far reaching consequences. It stands on an entirely different footing to the question of inheritance of other characters. That any other organ or character is inherited, provided that inheritance is not stronger for one value of the organ or character than another, is perfectly consistent with the organic stability of a community of individuals. That fertility should be inherited is not consistent with the stability of such a community, unless there be a differential death-rate, more intense for the offspring of the more fertile, *i.e.* unless natural selection or other factor of evolution holds reproductive selection in check. The inheritance of fertility and the correlation of fertility with other characters are principles momentous in their results for our conceptions of evolution; they mark a continual tendency in a race to progress in a definite direction, unless equilibrium be maintained by any other equipollent factors, exhibited in the form of a differential death-rate on the most fertile. Such a differential death-rate probably exists in wild life, at any rate until the environment changes and the equilibrium between natural and reproductive selection is upset. How far it exists in civilised communities of mankind is another and more difficult problem, which I have partially dealt with elsewhere. At any rate it becomes necessary for the biologist either to affirm or deny the two principles stated above. If he affirms them, then he must look upon all races as tending to progress in definite directions—not necessarily one, but possibly several different directions, according to the characters with which fertility may be correlated—the moment natural selection is suspended; the organism carries in itself, in virtue of the laws of inheritance and the correlation of its characters, a tendency to progressive change. If, on the other hand, the biologist denies these principles, then he must be prepared to meet the weight of evidence in favour of the inheritance of fertility and fecundity contained in Parts II. and III. of the present memoir.

The theory discussed in Part I. opens with the proof that if fertility be a function of any physical characters which are themselves inherited according to the law of ancestral heredity, then it must itself be inherited according to that law. As fertility would certainly appear to be associated with physique, we have thus an *à priori* argument in favour of its inheritance.

Further points dealt with are the influence of "record-making" on apparent fertility and fecundity. The fertility of mothers is always found to be more and their variability less than the fertility and variability of daughters. Accordingly from the apparent fertility and variability of the record the actual values in each generation must be deduced.

Methods are developed for finding correlation coefficients from the means of "arrays." These methods are of considerable importance, for they enable us to ascertain the correlation between a latent character in one sex and a patent character in another, or between characters latent in two individuals. Thus, it is shown that the correlation between the brood-mare's fecundity latent in two related stallions can be deduced from the correlation between the mean fecundities of their two arrays of daughters. In this way a numerical estimate can be formed of the inheritance of latent characters.

The effect of a mixture of correlated and uncorrelated material on correlation and variation is next investigated, and it is shown that the former is more seriously affected than the latter. Incidently the problem of the mixture of heterogeneous materials uncorrelated in themselves is investigated, and it is shown that a correlation will result in the mixture. This *spurious* correlation is of some importance for the question of mixtures of classes in fertility problems, but it is also significant of the general danger of heterogeneity in bio-statistical investigations, and further indicative of the possibility of creating correlation between two characters by breeding between small heterogeneous groups in which this correlation is zero.

Part II. of the memoir deals with the inheritance of fertility in man. It is first shown by large numbers that fertility is undoubtedly inherited from mother to daughter, but that if we include all types of marriages the inheritance is largely screened by other factors. An attempt is made to remove one by one these factors, and the more stringently this is done the more nearly the regression of daughter on mother moves up towards he value required by the law of ancestral heredity.

The inheritance of fertility from father to son is then considered; this is really rather an inheritance of sterility or tendency to sterility, for the full fecundity of a man is not usually exhibited in monogamic union. It is rather a problem of whether his fecundity lasts as long as his wife's. We find definite inheritance from father to son of this sterile tendency, although for the reason just given it falls below that indicated by the law of ancestral heredity.

Lastly, the inheritance of fertility in the woman through the male line is dealt with, and it is shown that a woman's fertility is as highly correlated with that of her paternal as with that of her maternal grandmother. In other words the latent character, fertility in the woman, is transmitted through the male line, and with an intensity which approximates to that required by the law of ancestral heredity.

Part III. of the memoir contains the results of a somewhat laborious investigation into the fecundity of brood-mares, which has been a number of years in progress.

(1) Fecundity in the brood-mare is inherited from dam to mare.

(2) It is also inherited from grand-dam to mare through the dam.

In both these cases the intensity is much less than would be indicated by the law of ancestral heredity, but the divergence is not such that it could not be accounted for by a percentage of fictitious values such as the peculiar conditions of horse-breeding warrant us in considering probable.

(3) The latent quality, fecundity in the brood-mare, is inherited through the sire; this is shown not only by the correlation between half-sisters, but by actual determination of the correlation between the latent character in the sire and the patent character in the daughter.

(4) The latent quality, fecundity in the brood-mare, is inherited by the stallion from his sire. This is shown not only by the fecundity correlation between a sire's daughters and his half-sisters, but also by a direct determination of the correlation between the latent quality in the stallion and in his sire.

In both these cases of latent qualities the law of inheritance approaches much more closely to that required by the Galtonian rule.

Parts II. and III. accordingly force us to the conclusion that fertility is inherited in man and fecundity in the horse, and therefore probably that both these characters are inherited in all types of life. It would indeed be difficult to explain by evolution the great variety of values these characters take in allied species, if this were not true. That they are inherited according to the Galtonian rule seems to us very probable, but not demonstrated to certainty. It is a reasonable hypothesis until more data are forthcoming.

PARIS.

Academy of Sciences, December 26, 1898.—M. Wolf in the chair.—Some peculiarities of the elasticity of muscle explained by comparison of the case of muscular substance in action with that of inert materials, by M. A. Chauveau. An experimental

[1] I have retained the term "reproductive" selection here, although objection has been raised to it, because it has been used in the earlier memoirs of this series. Mr. Galton has kindly provided me with "genetic" and "proliferal" selection. The term is used to describe selection of predominant types owing to the different grades of reproductivity being inherited, and without the influence of a differential death-rate.

comparison of the elasticity of vulcanised india-rubber with that of muscle in a state of physiological work. The results are expressed graphically in a series of six diagrams.—Histology of the skin: the epidermal fat of birds, by M. L. Ranvier. A study of the cause of the difference between the epidermal wax of mammals and the fatty material obtained from the feet of birds. A tangential section from the scaly portion of a chicken's foot, stained with osmic acid, showed that the epidermal cells are charged with liquid oily drops.—On a photograph of the nebula of Baleine obtained at the Observatory of Toulouse, by MM. Bailland and Bourget. The spiral in the nucleus, first described by Lord Rosse, is very clearly marked in the photograph.—Observations and elements of the new Chase comet, by M. G. Fayet.—On differential systems the integration of which can be reduced to that of total differential equations, by M. Riquier.—On differential equations of the first order, by M. Armand Cahen.—On linear total differential equations, by M. Alf. Guldberg.—On the velocity of sound in dry air at 0° C., by M. A. Leduc. A reply to the criticisms of M. Violle.—Influence of pressure on the initial polarisation capacity, by M. A. Chassy. Polarisation cells containing electrodes of various metals, as well as platinum black, were submitted to pressures ranging from 1 to 2000 atmospheres, without any appreciable change in the value of the polarisation capacity being noticeable. It is hence concluded that the phenomenon of initial polarisation does not correspond to an electrolytic decomposition into gaseous elements.—Radioconductors, with gold and platinum filings, by M. Édouard Branly. The use of gold powder for the preparation of tubes used in the detection of Hertzian waves has been negatived by Prof. Oliver Lodge; but the author finds, on the contrary, that although the successful use of tubes of this metal requires more delicate handling than other powders, this objection is more than counterbalanced by the extreme sensitiveness of the apparatus.—On a solution of the problem of multicommunication in telegraphy by the use of electric oscillations, by M. Albert Turpain. Having given several stations, A, B, C, . . . L, N, distributed along a single wire A N, the arrangement described permits of the simultaneous telegraphic or telephonic transmission of message between any pair of stations.—Remarks on the simple kathode rays, by M. H. Deslandres. A discussion of the views of M. Goldstein, and of his claims to priority on this subject.—On a new strongly radio-active substance contained in pitchblende, by M. and Mme. P. Curie and M. G. Bémon (see p. 232).—On the spectrum of a new radio-active substance, by M. Eug. Demarcay.—Researches on the separation and estimation of the halogen elements in their combinations with silver, by M. H. Baubigny. The mixed halogen silver salts are treated in the moist state with sulphuric acid and potassium bichromate at 90°–95° C. Under these conditions the iodide is quantitatively converted into iodate, and the chlorine and bromine set free. The test analyses are very satisfactory.—Action of oxidising agents upon some fatty and aromatic amines, by MM. Œchsner de Coninck and A. Combe. In presence of energetic oxidising agents the fatty amines are gradually decomposed, giving CO_2 and N_2. Under the same conditions the aromatic amines give colouring matters which are slowly decomposed with evolution of CO_2.—Thermal study of normal propylmalonic acid. Heat of formation of the solid potassium salt, by M. G. Massol.—On the oxidation products of oxygluconic acid, by M. Léon Boutroux. Oxidation with nitric acid gave racemic, trioxyglutaric, glyoxylic, and dioxybutyric acids.—The anti-virulent power of the serum of man and animals immunised against vaccinal or variolic infection, by MM. Béclere, Chambon, Menard, and Jousset.—On an example of *Dasypeltis scabra*, by M. Léon Vaillant. Fall of fossilised crustacean ostracods observed at Oullins, near Lyons, September 24, by M. Lortet.—Contribution to the study of the morphology of the Craspedomonadeæ, by M. J. Kunstler. On the presence of *Pinus sylvestris* in the quaternan gravels near Troyes, by M. P. Fliche. The remains found consist of the wood, roots, branches, bark, and cones, the latter being especially well preserved. The fossils do not occur in the base of the gravel, but are very abundant in the middle region.—On the discovery of graptoliths in the conglomerates of the vosgian grit in the neighbourhood of Raon-l'Étape, by M. Bleicher.—Appearance of the bear in the Miocene period, by M. Claude Gaillard.—On the folding of strata near Belledone, by M. P. Lory.—On the foldings of the Cretaceous strata of the Aquitaine basin, by M. Ph. Glangeaud.—On the origin of the iron ore of the Neocomian at Bray, by the superficial alteration of iron carbonate, and on the importance and continuity in depth of the carbonated ore, by M. W. de Mercey.—Observations by M. de Lapparent on the preceding paper. On the existence near Corinth of lherzolites identical with those found in the Pyrenees, by M. A. Lacroix.—On a new law relating to the grouping of crystals, by M. Fr. Wallerant.—New researches on a means of preventing oak wood from being worm-eaten, by M. Émile Mer.

DIARY OF SOCIETIES.

THE DEVELOPMENT OF RESEARCH.

The Discharge of Electricity through Gases. By Prof. J. J. Thomson, D.Sc., F.R.S. Pp. 203. (Westminster: Archibald Constable and Co., 1898.)

THIS work is an expansion of a series of lectures delivered at the University of Princeton, New Jersey, U.S.A., in October 1896. This practice of the American universities of inviting distinguished authorities to deliver courses of lectures is an admirable one. Lord Kelvin's Baltimore lectures were delivered under similar auspices, and it is to be hoped that the promised publication of these most interesting lectures will soon take place. By thus bringing our greatest living authorities into personal relations with the staff and students of a university an energetic stimulus is given to their studies and investigations. It might be said that the local staff and students can, if they wish, read the works of any authorities they desire to study. This is no doubt true, and it makes it now possible for each university by producing new knowledge to teach all the world, and not only those who come to reside in its vicinity. Thus the real students of each university are now spread all over the world and not confined to its precincts, as they were before the reproduction and distribution of thought was as easy a matter as it is to-day. And this is a great and important duty for universities, this producing and teaching new knowledge to mankind, but it is not their only duty. They should produce investigators and discoverers as well as investigations and discoveries. Under existing conditions, investigations and discoveries in the borderlands of science cannot reasonably be expected to lead to immediately useful results to mankind. They may be most useful to our grandchildren, but one cannot reasonably expect the ordinary motives of self-interest, to which the greater part of the good work of the world is due, to produce great work which may be of use to other people's grandchildren. For the production of such work, society, which has the greatest interest in the matter, must depend upon other motives for the production of great discoveries in pure science. The motives and abilities that must here be depended on do not exist in at all the same proportion of mankind as self-interest and that general ability to carry out rules which is sufficient for so much of the world's work. Enthusiastic devotion to the investigation and discovery of what is true, and the intellectual acuteness required for its successful pursuit, are not of common occurrence, and in a great many cases without special encouragement and training will, even in those who are capable of having these capacities highly developed, be overpowered by the distractions of other motives claiming attention to other fields of work. It is an important duty for universities to seek out those in whom it is possible to develop these motives and abilities; to encourage them to cultivate these abilities, and to strengthen in every way the hold of these motives on them. Almost the only way in which such motives can be strengthened is by the sympathetic encouragement of those who are already enthusiastic investigators and discoverers. That this is a really successful way of producing the character desired is fully proved by the existence of *disciples* in every branch of human endeavour that involves enthusiastic devotion of life. How is it that so many of the passing generation of chemical discoverers have been workers in the laboratories of Liebig, for example? The proportion of chemists who studied with Liebig to the whole body of those who have studied chemistry is very small indeed, but the proportion of leaders of chemical discovery who have studied under Liebig to the whole number of leaders of chemical discovery is quite large. Why? Because Liebig's example was catching, his personality was inspiring, his enthusiasm begot enthusiasm in his pupils; they became more than pupils, they became disciples.

It is in pursuit of this end that the American universities desire to bring their staff and students into personal relations with the leaders of thought. Though there is every prospect that they soon will be, they are not yet rich enough to control the market of English-speaking thought production by making permanent appointments, but they can and do provide for a temporary residence of a leader of thought amongst them. They do what they can to bring themselves into personal relations with those who are likely to stir their enthusiasm for research into useless truth, and thus strengthen the motive which distinguishes investigators and discoverers of the kind universities should produce.

These lectures are eminently inspiring. They are full of the seed from which discovery springs, of those sign-posts on the borderlands of the known which point out directions in which further knowledge is required. They call attention to important investigations now in progress, to the results so far achieved and to the results, too, that are still only probable and require further investigation. We do not generally get this in a book. We may find it in published papers, but we should find it in lectures delivered for the purpose of directing and encouraging the researches of others. So much of this is of only ephemeral value, though, like our dinners, of enormous importance for each day's work, that it is not usually published in book form nor often in scientific papers, notwithstanding such an illustrious example as Faraday. Working hypotheses, suggestions for work, all these may turn out wrong, or useless for further advance, but may be a very necessary part of the means of advancing. We eat much that we cannot assimilate in our dinners: it is a necessary concomitant of our food, and a reasonable quantity of it is possibly necessary for the satisfactory working of our organisms. Be that as it may, the question of real importance in working hypotheses is not so much, were they true, as, did they lead to advance towards truth. Very few, indeed, who have not suggested many wrong working hypotheses have advanced truth at all, and still fewer have had enthusiastic disciples.

In these lectures we have studies of the possible causes of atmospheric electricity depending on electro-superficial double layers, a subject deserving most careful investigation; studies of a remarkable penetration of kathode ray actions through such thick conductors that Lenard rays seem out of the question, and that raises the important question of the continuity or otherwise of the

discharge in gases; studies of the mysterious photo-electric effects at the surface of bodies and throughout the body of a gas, and that cloud-producing action which seems to provide us with the opportunity of isolating electrons, obtaining a drop of liquid with only one of these upon it; studies of kathode rays and of the velocity of the electric carriers in them. The argument by which, in this concluding study, there is an attempt to prove that these cannot be either larger than molecules, nor of a comparable size, is not particularly conclusive. Among the reasons given for concluding that these carriers are not larger, it is assumed that the resistance to their motion would obey the laws of motion of a body moving slowly through a viscous medium. This is not at all true of a minute projectile moving with a velocity of at least one hundred times the velocity of the molecules of the gas. To such a projectile the gaseous molecules would be practically at rest, and the resistance would be, as Lenard observed, proportional to the density of the gas. The argument against their being of a size about the same as that of the other gaseous molecules depends on the assumption that the effective size of a molecule is independent of its rate of motion, a conclusion which is at variance with the known laws of diffusion of gases at various temperatures, and is contrary to such a probable hypothesis as that the actions between molecules is more like that between centres of force with rapidly changing forces near them than like that between hard spheres. For a comet to be deflected by a given amount when going near the sun, it should pass much closer to the sun if its velocity is large than if its velocity is small. The effective size of the sun as a deflecting cause for comets very largely depends on the velocity of the comet. On these principles rapidly moving molecules might go much further through a gas than the free path of an ordinary molecule. When the disagreement between the theory of hard spheres and the observed laws of diffusion at different temperatures is measurable, and it only corresponds to alterations of velocity to about twice the normal, we may naturally expect great variations when dealing with velocities of about one hundred times the normal, which would correspond to a temperature of some 2,000,000° C.

At the same time, there is a good deal of other evidence in favour of the suggestion that in kathode rays we are dealing with carriers of smaller mass than atoms. One would naturally conclude that we were here dealing with what might be described as disembodied electrons, *i.e.* with electrons separated from the atoms with which they seem in general so intimately connected. Most theories of electrolysis assume that an electron can be transferred from the atom in the liquid to the plate, and almost any theory of metallic conduction must involve the transference of electricity from molecule to molecule in the conducting solid. The only difference between these cases and that of the supposition that kathode rays are torrents of electrons is as to the distance the electron can travel from molecule to molecule. If it can ever leave one molecule to join on to another, why may it not jump some centimetres of space between them? This reconciles to some extent the radiant matter and pure ether theories of the kathode rays. It makes them essentially an ether phenomenon, while at the same time they are streams of particles: it makes them light on the emission theory.

It ought to be possible to test whether these emissions are material or not, by collecting them in a small vacuum tube. It is not generally appreciated how very small a mass of gas there is in a small highly exhausted vacuum tube, though it contains enormous numbers of molecules. At the pressure of a millionth of an atmosphere, which is quite a large pressure of about a dyne per sq. cm., there could be collected in a few minutes in a tube of several cubic millimetres capacity a quantity of hydrogen which it would require 100,000 years collecting at the same rate in order to collect a gramme of it.

In every way the book is suggestive, interesting, and inspiriting, and as such should fulfil its purpose of provoking research and advancing science.

GEOMETRY OF POSITION.

Lectures on the Geometry of Position. By Theodor Reye, Professor of Mathematics in the University of Strasburg. Translated and edited by Thomas F. Holgate, M.A., Ph.D., Professor of Applied Mathematics in North-western University. Part I. Pp. xix + 248. (London: Macmillan and Co., Ltd. New York: The Macmillan Company, 1898.)

AT last there is an English edition, translated in America, of the first part of Prof. Reye's "Geometrie der Lage," of which the first edition appeared as long ago as 1866. The methods followed offer so many advantages, and the style adopted is so lucid, that we heartily welcome this translation, and we with confidence express the hope that it will awaken new interest in the study of this charming subject in this country as well as in America.

The book owes its origin to lectures delivered to engineering students at the Polytechnic School at Zürich. They were undertaken with the view of giving the students that geometrical knowledge which they required in order to listen with advantage to Culmann's lectures on graphical statics.

Culmann based his new science upon the very abstract "Geometrie der Lage" by Von Standt, and this prescribed the course which Reye had to follow. He did so willingly, and says in the preface to the first edition:—

"One principal object of geometrical study appears to me to be the exercise and the development of the power of imagination in the student, and I believe that this object is best attained in the way in which Von Standt proceeds."

The object of Reye's lectures, therefore, is not only to impart knowledge of conics and quadric surfaces, &c., but also and especially to educate the student's mind in the faculty of easily and readily realising geometrical figures in space, a faculty very important to engineers.

"Geometry of position," as opposed to "metric geometry," with which alone Euclid deals, excludes all measurement. But whilst the older authors and founders of this modern science based it on Euclidian propositions, Von Standt has shown that these can be altogether avoided, and Reye follows this course rigidly.

Here everything is based upon harmonic points in a range, and harmonic rays in a pencil, or, as the translator calls it, a sheaf.

All the previous knowledge needed consists of a clear notion of the concepts of point, line and plane, and their fundamental properties, such as the propositions that two points determine a line, two planes meet in a line, &c., together with a power of imagining these elements in their mutual relation in space; for instance, that a line may lie in a plane, or else can cut it in one point only.

These ideas being in the mind of the reader, nothing more is required, and they will themselves gradually become developed and gain in clearness as he proceeds.

It goes without saying that such a system requires a number of new concepts; namely, those of the primitive forms, "the elementary prime forms" in Leudesdorf's translation of Cremona's "Projective Geometry." These are explained in Lecture i.

In the second lecture the correlations between the prime forms as given by projections and sections are considered, and these lead to the ideal elements at an infinite distance. By their aid the exceptions due to parallelism are got rid of. At the same time a first instance is given of the leading principle of "correspondence" between the elements in two or more prime-forms.

In Lecture iii. the principle of duality appears as a natural and simple consequence of the first and fundamental properties of the elements.

After these preliminary lectures we come in the next to "harmonic forms," which are deduced by aid of certain simple constructions in three dimensions without reference to measurement. There is added a discussion of their metrical properties.

In the fifth lecture we have the projective properties of primitive forms, and the all-important principle of correspondence between the elements in two of them. It ends with the generation of curves of second order and second class, respectively, by projective ranges and sheaves (flat pencils), the actual construction of points on, or tangents to such curves being given.

With this the reader has finished the preliminary work. It may at first have appeared to him somewhat tedious, as he is unable to appreciate the usefulness and fertility of the definitions and methods explained. He has acquired many definitions and plenty of new ideas, but not as in Euclid at every step a tangible result. This is now all changed. The next chapter shows that the time and trouble expended are to be amply repaid, for now the study of the curves mentioned begins, and he is told that these curves are the conic sections. Side by side with these go the generation and the properties of cones of the second order, and cones of the second class, but these are at once dropped, as their properties are an immediate consequence of the curves. The latter are now investigated in detail. Their construction is more closely examined, and leads almost at once to the celebrated theorems of Pascal and Brianchon. It also follows that five points or tangents determine a curve of the second order or class.

The fact that these fundamental properties appear at the very beginning is characteristic of the whole method, and this shows that the method is a natural one.

In the seventh chapter the more immediate consequences of these theorems is considered. The curves are also classified as ellipses, hyperbolæ, and parabolæ, according to their elements at infinity.

In Chapter viii. the special case of Pascal's theorem when the hexagon is reduced to a quadrilateral leads to the theory of pole and polar, and these are in the next lecture specialised by aid of the lines and the points at infinity so as to give the properties of centres, diameters, and axes of conics. In this lecture, too, the equations of the conics are obtained, and thus the proof is given that the conics studied by aid of coordinate geometry are the same as those here considered.

Of course the principle of duality is constantly used, and properties of curves of second order and second class are treated simultaneously till in Lecture vii. their identity is proved. Numerous other theorems of conics are given at every stage, but we have only mentioned a few in order to show the sequence in which they follow.

Of this enough has been done, and the contents of the rest of the book can be dealt with more summarily.

Lecture x. treats of the ruled quadric surfaces; the next of projective relations of "elementary forms," viz. the range, the sheaves, curves and cones of second order, and the ruled quadric surfaces.

These relations lead to the "theory of involution," Lecture xii. The metric properties are considered in Lecture xiii., and applied to establish the *focal properties* of conics; whilst in Lecture xiv. problems of the second order are solved, and "imaginary elements" introduced in the manner of Von Standt. By their aid problems are solved by actual construction on the drawing board, in which among the given data are "imaginary" elements; for instance, the problem of drawing a conic which passes through three given points, and the two points in which a given line cuts a given conic in the case where these points have no actual existence.

It will be seen that hereby again the greatest generality is obtained, and that the exceptions which would occur if the different case where the line cuts the conic, touches it, or does not cut it, are to be treated separately.

In the fifteenth and last lecture, principal axes and planes of symmetry, focal axes, and cyclic planes of cones of the second order are dealt with.

This finishes the first part of Reye's work, which is restricted to the investigation of curves and surfaces generated by projective primitive forms of one dimension, the range of points, the sheaf of lines and the sheaf of planes, that is the range and the flat and axial pencil.

The projective and primitive forms of two dimensions give rise to quadric and cubic surfaces and twisted cubic curves, whilst the forms of three dimensions, viz. the space with points and planes as elements lead to the theory of co-linear and reciprocal spaces. These form the contents of Vol. ii. The translator does not say anything about it, but as the volume before us is marked both on the title-page and the back as Part i., there seems reason to hope that the translation of the second part will soon follow.

There is, however, an appendix to Part i., which has still to be mentioned. It contains an account of the principle of reciprocal radii, Dupin's cyclide, ruled surfaces of the third order, quadrangles and quadrilaterals, which are self-polar with respect to conic sections, and lastly a pretty full, though condensed, account of nets and webs of conic sections.

The translation is very well done. It has evidently

been a labour of love to Prof. Holgate. He has, however, in the terminology departed somewhat from that which has been used in this country. He has altogether eschewed the word "pencil"; instead of it he uses for the flat and axial pencils "sheaf of rays" and "sheaf of planes," thus appropriating the word sheaf to one-dimensional forms, whilst it has in England been used for pencils of lines and planes in space. For these he takes the word "bundle," thus adopting the German phraseology. We think it is a pity he has made this change, not because the old terminology is better, but because it makes the adoption of a uniform system more difficult.

The translator has made a few changes from the original. He has broken up the lectures into articles which he has numbered, and he has placed the numerous exercises at the end of each lecture to which they belong, instead of leaving them together at the end of the book as in the original. He has also added an index. These are decided improvements. In his preface he gives a short account of the history of projective geometry.

As far as the paper, the printing and the figures are concerned, the book ranks among the best we have seen; in these respects it is, in fact, above praise.

We recommend the book to *all* students of mathematics, and advise them not only to read it, but also to actually make accurate drawings of at least a great number of figures; especially to construct a variety of conics from given conditions, and to solve as many as possible of the problems proposed. These constructions should be made accurately on the drawing board. They offer a wonderful incitement to accuracy and neatness, as every fault in drawing becomes at once evident to the eye. For this reason the schoolmaster who has to teach mathematics and geometrical drawing on the modern or science sides of schools, will find it of great advantage in his teaching. The book will afford him innumerable examples for geometrical drawing, even if he cannot much hope to enter at present on teaching the theory: although there is no reason, as far as the difficulty of the subject is concerned, why he should not introduce a good deal in the higher forms. It is most stimulating to young students, as is evidenced by the fact that students have repeatedly told us that, although at school they could not take any real interest in Euclid, and found geometry very hard, they found the theory of conics as treated according to Reye delightfully easy and interesting. In fact, the subject is full of life; the figures grow organically one out of the other, and the Propositions arrange themselves in a natural sequence. O. HENRICI.

RACIAL ANATOMY.

Observations sur les Variations Musculaires dans les Races Humaines. Par Théophile Chudzinski. Memoires de la Société d'Anthropologie de Paris, Ser. 3; t. ii.; fasc. 2. (Paris, 1898.)

THIS posthumous work of Chudzinski is a laborious and systematic attempt to open up quite a new field of anthropological investigation. It may be said, with perfect truth, that the study of the various races of mankind has been superficial and empirical; observations hitherto have been confined to features, colour of skin, size of body, proportion of limbs and bone measurements. With the exception of the late Prof. Giacomini of Turin, Chudzinski is practically the only man that ever went beneath the skin to discover the real and essential features that separate one race of man from another. There is no desire here to minimise the value of the few briefly recorded dissections, made on dark-skinned waifs that have died in Europe, and found scattered in the anatomical literature of the present century; the observations on the brains of negroid races by Parker, Broca, Gratiolet, Waldeyer, Marshall, Tiedemann, Calori and Barkow are good so far as they go, dissections of individual specimens made by Flower and Murie, Cuvier and Turner, are efforts in a right direction, but the merit of having opened up a systematic investigation of the anatomy of the races of mankind, taking a group of individuals to represent the race, remains to Chudzinski and Giacomini. This treatise is a record of the muscles of ten negroes, five negresses, five individuals belonging to yellow-skinned races, contrasted with the muscles of six individuals of a white-skinned race.

The result of this laborious investigation is to show that, on an average, in size, in proportion of flesh and tendon, in relative and absolute extent of attachments, the muscles of Chinamen, Frenchmen and negroes are very different. Unfortunately, Chudzinski's methods are open to serious criticism. Take his account of the *soleus* muscle as an example; it is a muscle peculiarly adapted in men for erect progression. He gives in millimetres the extent of its attachment to the fibula: the extent of origin in white men is 135 m.m.: in yellow races, 97 m.m.; in negresses, 94·5 m.m.; in negroes, 120 m.m.: the extent of origin is greatest in white men, as one would expect, but it is obvious that a great error is introduced if no account is taken of the size and stature of the individuals compared, and of this factor Chudzinski has taken no cognisance. Only here and there are relative measurements given. Yet on the whole there can be no doubt that Chudzinski has, in his minute analysis of the muscular system, discovered very numerous features wherein the white, the yellow and the black man differ, and his results may be summarised by saying that, on the whole, the muscular arrangement in the white man is more accurately and powerfully adapted for erect progression of the body and precision in the use of his hands than in the negro, and in some points, although by no means in all, the muscular system is rather more simian in the negro than in the white man.

But by far the most valuable part of Chudzinski's work lies in his observations of muscular anomalies. Adding his work to Giacomini's it may be said, without any danger of over-stating the case, that the negro shows in his muscular anomalies twice or three times the number of simian characters met with amongst white men. Looking at it from the point of view of descent, the negro has retained certain primitive features much more than the white races, among them his black colour.

Little notice was taken in this country of Chudzinski's death, which took place in Paris some eighteen months ago. He was born a Pole, and, when a student at Moscow University, became involved in the insurrection of 1863, and, like many of his countrymen who afterwards became known in science, sought refuge in Paris.

He became laboratory assistant to Broca, and afterwards one of his ablest disciples. He was always extremely rich in modesty and poor in means; spent his life unostentatiously and contentedly plodding through a wilderness of dry detail to gather a handful of generalisations such as may be seen in this his last work.

OUR BOOK SHELF.

An Experimental Course of Chemistry for Agricultural Students. By T. S. Dymond. Pp. 192. (London: Edward Arnold.)

THE attempt is often made to teach agricultural science to students who have received no previous scientific training; the results of such an attempt are usually very unsatisfactory. Agricultural problems are indeed highly complex, and if the student is to understand the investigations which have been made to solve them, and is rightly to appreciate the results, he must be first acquainted with the laws and facts of nature which are involved in the phenomena under consideration. The teaching of pure science must thus always precede the teaching of applied science. Technical instruction given alone, can only consist of a series of directions and prescriptions, which are necessarily of very limited value. As soon as a scientific exposition of the subject is attempted, the preliminary study of pure science becomes essential to success.

The book before us is an introduction to chemical science, intended for students who are about to study the chemistry of agriculture. The course of instruction is intended to be given in a chemical laboratory, and the greater part of the experiments are to be performed by the students themselves; this is undoubtedly the best way of learning a science. Mr. Dymond is much to be congratulated on the very carefully constructed scheme of work which he has now published; its practical merits are doubtless to a considerable degree due to the fact, mentioned in the preface, that the scheme has been in use during the past three years in many evening schools and classes in the County of Essex; the ideas of the author have thus been gradually perfected by practice. The course is intended as an introduction both to inorganic and organic chemistry. The subjects selected for the various lessons are, when possible, of an agricultural character. Too much is sometimes attempted in this direction. Subjects such as the physical properties of soil, and the composition and properties of milk and butter, fully deserve to be treated of in several lessons, instead of the present brief notes in small type. The two pages on the chemistry of animal and vegetable life are a further example of the inadequate treatment of subjects which really lie outside the scope of the present course. Mr. Dymond would do well to write a second course of instruction, to follow that which he has now published; in this the problems of agriculture could be made the principal subjects of study. We can cordially commend the book. R. W.

Gesammelte Botanische Mittheilungen. Von S. Schwendener. Two volumes. Pp. iv + 453 and 419. (Berlin: Gebrüder Borntraeger, 1898.)

THE last few years have seen the appearance of "collected works" of more than one eminent German botanist, and all students in the science will welcome the newest addition to this form of literature.

Truth to tell, Prof. Schwendener's work has hardly met with the general recognition it deserves. Of course every one is familiar with his relation to the lichen controversy, and most of us have doubtless a more or less intimate knowledge of his work on the ascent of sap. Of his other writings, especially on physical matters many have but a very scant acquaintance, and even the anatomical papers are not as widely read as they deserve.

In a great measure this is no doubt due to the medium which Dr. Schwendener commonly selected for publication, which prevented their free circulation amongst fellow students; but now they are rendered accessible, they will assuredly command more attention at first hand. For there is an immense amount of valuable and interesting matter contained in the bulky volumes before us, even though it is not always possible to follow the author's meaning with ease, owing to his somewhat difficult style.

The papers are all accurate reprints (with the plates) of the author's works which have been published since 1879; but where his views have undergone modification since the appearance of any paper, readers will find his present opinions stated in the appendices which are added at the end of the text.

As the papers have thus appeared for some time, it is not necessary to discuss their contents here; and it may suffice to say that they deserve, and doubtless will obtain, an honoured place in every botanical library.

Die Bewegung im Weltraum. Von E. Kethwisch. Pp. 184. (Berlin: Schneider, 1896.)

THIS book contains a criticism of the theory of universal gravitation, although it does not deny that Newton explained the harmony of the universe with mathematical exactness. A statement of a few of the conclusions at which the author arrives, will probably suffice for the readers of NATURE.

According to the theory of gravitation the sun maintains the planets in their orbits; but what is the force that prevents the sun moving off into space? The theory demands some larger body which shall hold the sun, this new body demands another, and so *ad infinitum.* The theory of gravitation is thus reduced to an absurdity.

On p. 23 we learn that the number of oscillations of a pendulum is quite independent of the force of gravity. In fact, that theory demands that a heavy body shall attract another with greater force the lighter is the latter.

The attraction of Schehallien, as observed by Maskelyne, was due to magnetism; and if Cavendish had made his celebrated experiment with non-magnetic bodies, he would not have detected any attraction.

The discovery of Neptune affords no proof of the theory of gravitation. The received theory of the tide is absurd, as lunar attraction cannot possibly cause the semi-diurnal tide. The force of gravity on any planet is wholly due to its rotation, and its intensity is directly proportional to the *linear* velocity of a point on the equator.

It is probable that this work contains many other remarkable propositions; but the writer of this notice did not read to the end.

Small Accumulators. How Made and Used. Edited by Percival Marshall. Pp. 62. (London: Dawbarn and Ward, Ltd.)

THIS is the first of a series of small and popular scientific manuals for amateur electricians and students. The instructions are sufficient to enable small accumulators to be constructed by readers who have not any previous knowledge of electricity; and for readers who prefer to purchase these appliances, descriptions are given of several forms of storage battery.

Natalité et Démocratie. By A. Dumont. Pp. 230. (Paris: Schleicher Frères, 1898.)

THE six lectures printed in this volume were delivered at the Paris École d'anthropologie during the session 1896–97. They are all concerned with the subject of depopulation in France, variations of the birth-rate in different districts, and the importance of the effects upon national welfare.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

In a recent issue of the *Journal of the Linnean Society* (Zoology, No. 172) there is a short paper by my friend Dr. St. George Mivart, in which he gives numerous cases of species of Lories peculiar to various Papuan or Pacific Islands, which differ in some details of coloration from allied species in other islands, while they are usually altogether unlike the other birds inhabiting the same island. He then argues, as Captain Hutton had done with regard to similar phenomena among the fruit pigeons of the genus Ptilopus, that these various specific markings cannot be useful, and especially that they cannot be needed as "recognition-marks," because the whole coloration of the genus is so distinct that they cannot possibly be confounded with any other birds now inhabiting the same islands. He therefore concludes that these facts "are fatal to a utilitarian explanation of the origin of all specific characters." At the same time he accepts evolution and the natural biological origin of these and all other characters. These conclusions appear to me to be wholly illogical and to be reached by omitting to take account of the fundamental idea of organic evolution itself, namely, that each species has been, somehow, developed from an allied but distinct species, living or extinct. I therefore ask leave to point out how this omission affects the problem.

It is quite clear then that each distinct species of lory or fruit pigeon now found isolated from their allies in so many of the Pacific Islands *must* (if evolution is admitted) have originated by modification from some other parent species. The modification may have occurred in another island (or continent) or in the island in which the modified species now exists; but, in either case during the process of differentiation, recognition-marks would be of vital importance by checking intercrossing, so much so that it is doubtful whether in many cases the required structural or physiological modifications could be brought about without them. I do not remember that this proposition has been seriously denied, and it is the omission to take account of it that invalidates the argument of Dr. Mivart and Captain Hutton, founded upon the existing distribution of the species in question.

Perhaps these gentlemen will reply that they hold the views of Romanes and Gulick, that the specific differences in question are the direct result of the action of changed conditions on the progeny of the individuals which first reached the islands; but this theory is a pure assumption in support of which I am not aware that any adequate facts or observations have been adduced, while such changes in *all* the individuals exposed to the influence of the new conditions is entirely opposed to the known facts of variation. Supposing, however, that the existing species originated in the islands where they now occur by modification of some two or more original immigrants, let us consider *how* the change would be effected in accordance with the known facts of variation and natural selection.

The first thing that happens on the introduction of a new form into an island well-suited to it, and with no other enemies than those to which it is already adapted, is to increase rapidly till the island is fully stocked—witness the rabbit in Australia, New Zealand, and Porto Santo, the sparrow in America, and numerous other cases. But as soon as the island is fully stocked and all future increase dies off annually, natural selection begins its work, and the least adapted to survive, in every stage from the egg to the parent birds, get destroyed by some means or other. Now, if this process of elimination is identical in character with that to which the species was subjected in its former home no specific change will take place, because the whole structure and habits which constituted "adaptation to conditions" in its former habitat are equally effective in its new abode. But if there is any difference in the environment which requires a new adaptation, whether as regards food, seasons, diseases, or enemies of other kinds, then natural selection will certainly tend to bring about that new adaptation, and as in such a limited area local segregation will be ineffective, some external indication, marking off the new and better adapted from the old less adapted type, will be of the first importance in the prevention of inter-crossing and thus hastening the process of complete adaptation; and these external indications are what I have termed "recognition-marks." When the new type is fully established and the old parent-form has died out, the work of these recognition-marks will have been done; but having been established by a severe process of selection they have become fixed and continue to form the "specific character" distinguishing the new from the old species. The repeated statement of Dr. Mivart, that in this or that case the peculiar marking cannot be a recognition-mark, or that such "recognition-marks" are quite needless, is therefore beside the question, since the very existence of the new species during the process of differentiation may have depended upon them.

I have here confined myself strictly to the one point raised by Dr. Mivart and Captain Hutton, having already dealt with the general question of "utility" elsewhere.

ALFRED R. WALLACE.

The Duke of Argyll and Mr. Herbert Spencer.

In his review of the Duke of Argyll's "Organic Evolution Cross-examined, &c.," Prof. Meldola describes the Duke as "doing violence to Huxley's teaching," and asks him "in fairness" to "reperuse" something Huxley has written. After recognising the unfairness he refers to, he might not unfitly have suspected unfairness in the Duke of Argyll's representations of my views: especially considering the absurdities ascribed to me. Yet Prof. Meldola says that the Duke "makes some good points out of Mr. Spencer's change of view with respect to the efficiency of natural selection," and represents him as making merry "over Mr. Spencer's abandonment of that excellent child of his creation, the term 'survival of the fittest.'"

Had Prof. Meldola looked into the matter, he would have found that I have in no degree whatever abandoned the term "survival of the fittest." The Duke of Argyll has misrepresented me in a way which is extremely surprising. In the "Factors of Organic Evolution" ("Essays," i. 429-30), after pointing out that the metaphorical character of Mr. Darwin's expression "Natural Selection" is apt to mislead, as he himself admitted, I said that "kindred objections may be urged against the expression 'survival of the fittest.'" I said that "survival" "suggests the human view of certain sets of phenomena" rather than the view of them as physical facts; and I further said that "If a key fits a lock, or a glove a hand, the relation of the things to one another is presentable to the perceptions. No approach to fitness of this kind is made by an organism which continues to live under certain conditions" (p. 430). But there is no admission that the words, imperfectly adapted as they are, fail to express the truth in question with approximate correctness. Any one who will turn to the chapter on "Indirect Equilibration," in vol. i. of the "Principles of Biology" (§ 164), will read as follows:—

"That is to say, it cannot but happen that those individuals whose functions are most out of equilibrium with the modified aggregate of external forces, will be those to die; and that those will survive whose functions happen to be most nearly in equilibrium with the modified aggregate of external forces. But this survival of the fittest implies multiplication of the fittest, &c."

It was in this place and in this manner that the expression "survival of the fittest" arose, and to show that I have abandoned the belief it formulates it is needful to show that I have abandoned the theory of indirect equilibration which it is used to express briefly. I have done nothing of the kind, and there is no sign that I have done anything of the kind.

I am, indeed, not a little astonished that the Duke of Argyll should have reproduced these statements of his after the direct contradiction given to them in my reply to him published in the *Nineteenth Century* for February 1888. At the close of my article, entitled "A Counter Criticism," there occur the sentences:—

"On one further point only will I say a word, and this chiefly because, if I pass it by, a mistaken impression of a serious kind may be diffused. The Duke of Argyll represents me as 'giving up' the 'famous phrase,' 'survival of the fittest,' and wishing 'to abandon it.' He does this because I have pointed out that its words have connotations against which we must be on our guard, if we would avoid certain distortions of thought. With equal propriety he might say that an astronomer abandons the statement that the planets move in elliptic orbits, because he warns his readers that in the heavens there exist no such

things as orbits, but that the planets sweep on through a pathless void, in directions perpetually changed by gravitation."

It remains to remove a misapprehension of Prof. Meldola's own. He says: "It may be well to indicate that many—perhaps we may say the majority of biologists in this country—have long ago parted company from Mr. Spencer on this question of the enhanced importance of 'direct equilibration,' and the subordinate position assigned to 'indirect equilibration' in his later writings." I know of no foundation for such part of this statement as refers to my opinions. That I have not changed my view concerning the respective shares of direct and indirect equilibration there is incontestable proof. If Prof. Meldola will turn to § 170 (p. 468) of the "Principles of Biology," first edition, he will find it there contended that at first "natural selection worked almost alone in moulding and re-moulding organisms into fitness for their changing environments; and natural selection has remained almost the sole agency by which plants and inferior orders of animals have been modified and developed." He will find it further said that in proportion as organisms become complex and active, "the production of adaptations by direct equilibration takes the first place—indirect equilibration serving to facilitate it." And now, if he will turn to the revised edition of the "Principles of Biology" issued last year, he will find that the two sentences quoted stand as they did in 1864.

Prof. Meldola has been misled by a not unnatural illusion. I have of late years had occasion frequently to insist on the share taken in organic evolution by direct equilibration (or the inheritance of functionally-produced changes) because it has been continually denied; and frequent insistence on its share has been mistaken for an alleged extension of its share.

Brighton, January 8. HERBERT SPENCER.

Carte Géologique internationale de l'Europe.

I HAVE just received, through Mr. Edward Stanford, Livraison iii., containing seven sheets of this great work, in which we have the maps of the British Isles, of Germany, Italy, Austro-Hungary and Greece. These maps exhibit a marvellous amount of care on the part of the Directors, and of elaborate execution on the part of Herr Dietrich Reimer and his staff. I do not venture to eulogise, much less to criticise the maps, but only to direct attention to one special point of interest which they exhibit, namely, the representation of the great terminal moraines on both sides of the Alps. It requires a little close scrutiny to discover the course of these great banks of glacier detritus laid down at the epoch of greatest cold of the Glacial Period; but once recognised, it amply repays attention to follow their course. They are represented by lines of purple dots, about three or four deep, lessening in size inwards; and, of course, passing disconnectedly over all the geological formations. On the north base of the Alps the moraine bank starts from above Grenoble, swelling northwards near to Lyon along the Rhône valley; then, retreating southwards, it winds along the flanks of the Jura above the plain of Geneva and Lake Neuchâtel; then passing by Berne and Zürich, stretches away northwards by Schaffhausen and Ravensburg, indicating the enormous extent of the old Rhein Glacier; and then curving outwards along the valleys descending from the eastern Alps by Munich and Salzburg, it is represented as surrounding the northern shore of the Traun See; but no further eastwards.

The northern limit of erratic blocks is represented by a nearly continuous red line extending generally much further from the base of the Alps than is the case with the terminal moraines. Commencing on the west at Grenoble the line curves round by Lyon and Bourg, and then ranging along the Jura Meridional, celebrated for the huge boulders of granite which are there stranded, stretches northwards towards Besançon; thence, skirting the Rhein valley near Basel, the line stretches eastward by Schaffhausen, where it almost skirts the northern base of the moraine, and so passes onwards by Munich to the banks of the Enns by Steyr (Steyer).

The great glaciers which descended from the Alps on the Italian side have (as is well known) left behind them huge moraines, which are also represented in a manner similar to those on the north side. Thus we have the great terminal moraines of the rivers Dorea Riparia and Dorea Baltea near Turin; then, further eastwaid, those which border the southern shores of Lakes Maggiore, Como, D'Iseq and Garda. The southern limit of erratics is only represented at a few places, and then generally in close proximity to the margin of the moraines. The close connection of the great Italian lakes with the moraines cannot be overlooked by those who recognise the evidence adduced by the late Sir A. C. Ramsay in support of his views on the glacial origin of lakes. The moraines of the Dorea Riparia and Dorea Baltea were amongst his favourite illustrations.

Before closing I might be allowed to add that the topography of the map is admirable, while the coloration of the geological formations, except, perhaps, in the case of the British Isles, fully sustains the reputation of the Lithographic Institute of Berlin. EDWARD HULL.

January 3.

Periodic Tides.

CAPT. A. S. THOMSON (p. 125) calls attention in your columns to the subject of short period oscillation of water-level at Malta and Sydney, and asks for further information from others. As I have given some attention to studying similar phenomena on the eastern coast of Canada, I venture to offer the following additional information and suggestion of an explanation.

(1) The phenomena are very common. At St. John, New Brunswick, on the coast of the Bay of Fundy, the oscillations have a fairly constant period of 43 minutes. At Quaco, a few miles further up the bay, the period is only $12\frac{1}{2}$ minutes. At Halifax, Nova Scotia, on the Atlantic coast, the period is $23\frac{1}{2}$ minutes. In the Gulf of St. Lawrence, at South-West Point (Anticosti), the oscillations are rapid but irregular; at St. Paul's Island, very rapid and irregular; at Forteau Bay, small and irregular; at Carleton (Quebec) there is some indication of a 22-minute period; at Souris (Prince Edward Island) the oscillations are rapid and irregular; at Pictou (Nova Scotia), small and irregular: at St. Peter's Island, very rapid and irregular.

(2) Any explanation must account for two distinct things: the *origin* of the fluctuations, and their *periodicity*. Let us take these in reverse order.

(3) The period of the oscillations (where they have a definite period) is, I believe, simply the period of the free natural vibrations of a semi-confined body of water "wish-washing" to and fro like water in a wash-bowl, the oscillations being sometimes *fundamental*—that is, consisting in the vibration of the body of water as a whole; and in other cases (perhaps the majority of cases) *partial*—that is, due to the body of water dividing up into two vibrating halves, or three-thirds, &c. In a very irregular basin, like the Gulf of St. Lawrence, regular vibrations are impossible. In some other cases the basin is of sufficiently regular form to admit of fairly regular oscillations, but not regular enough for the period to be deduced mathematically. In only two cases have I found a mathematical test possible. At St. John, the Bay of Fundy is bounded on one side by the slightly indented New Brunswick coast, and on the other side by the straight, abrupt Nova Scotia coast, these two shores being only slightly inclined to one another. The width may be taken as forty miles, and a study of the chart gives the mean depth *at low tide* as 34·4 fathoms. The period of fundamental vibrations across such a basin is given (to a sufficient approximation) by

$$t = \frac{2l}{\sqrt{gh}},$$

l being the width, and h the mean depth. With the above figures, this gives for fundamental vibrations a period of 87 minutes, and for first partial vibrations a period of 43·5 minutes. The latter is remarkably close to the observed period of 43 minutes. It should be noted that the calculation applies to low tide. Now, the tide at St. John has a range of 20 feet, while the formula shows that the period vaiies inversely as the square root of the mean depth. A simple calculation shows that the period at high tide should be two minutes less. From an examination of all the cases available, I found that the mean period for high tide was actually 1·6 minutes shorter than for low tide; but the fewness of the well-marked cases available to me for making this test (thirteen in all) makes me believe that this agreement is somewhat accidental.

The other case known to me to which a similar calculation can be applied, is that of a small basin in the St. John River, just before it flows through a very narrow gorge into the harbour. While using a rough form of self-recording tide gauge for finding accurately the time of high water, I discovered on the

record, not only the above-mentioned 43-minute oscillations, but also a series of much more rapid oscillations having a period of about 35 seconds (the latter figure being obtained by a stop-watch). The width of the basin is, at the point of observation, 2030 feet, and its mean depth about 100 feet (the tidal range is less than 2 feet). Calculation by the above formula gives, for first partial vibrations, a period of 35·8 seconds, which is very close to the 35 seconds observed; but it is to be noted that for a basin whose depth is *not* small compared with its width, the above formula is somewhat in error, and a more correct formula (involving a hyperbolical cotangent) gives 37·5 seconds. In any case the agreement is striking, and the two instances given are almost conclusive as to the explanation advanced. Simultaneous observations on opposite sides of such a basin would be quite conclusive, but these I have not yet had an opportunity to make.

(4) The following notes on the other cases referred to in (1) may be of interest in connection with observations referred to by Capt. Thomson. Quaco is only about twenty miles further up the Bay of Fundy than St. John, and yet, while expecting to find there a period similar to that at St. John, I found a period of 12½ minutes (from four separate records). This was at first puzzling, but, later, an examination of the chart showed the existence of a dangerous ledge (the Quaco Ledges) coming nearly to the surface, at a distance of eight or ten miles off shore, and forming, with a headland above Quaco and another below, an irregular basin, the dimensions of which no doubt determine the period of oscillation. A quite similar explanation applies to the oscillations at Halifax, for there a succession of banks (the Emerald, Sable Island, Le Have and Roseway) form, with the Nova Scotia coast, a large-sized bay of irregular shape.

(5) As to the external impulse that starts the oscillations, there is much uncertainty. Marked oscillations at St. John are frequently accompanied by barometric disturbances, but not always. My own observations make me believe that the oscillations and heavy ground-swell usually coexist. A notable case (for which I have to thank Mr. S. W. Kain, of St. John) occurred on September 18, 1898, when the heaviest ground-swell in several months was accompanied by marked periodic oscillations recorded on the Kelvin gauge. On the whole, I believe that the disturbance of equilibrium is due either to abrupt local variations of atmospheric pressure, or to the transmitted effect of a distant hurricane.

Those who are interested in this subject will find fuller details of the cases here discussed numerically (and also a short bibliography of the subject) in a paper by myself in the *American Journal of Science* (vol. iii., 1897). The nature of the oscillations in the Gulf of St. Lawrence are shown on curves that illustrate a tidal report, by Mr. W. Bell Dawson, in the last volume of *Transactions* of the Royal Society of Canada (see NATURE, vol. lviii. p. 260).

A. WILMER DUFF.

Purdue University, Lafayette, Ind., U.S.A.

GENERAL LAW OF THE PHENOMENA OF MAGNETIC PERTURBATIONS OF SPECTRAL LINES.

In the *Philosophical Magazine* for April 1898, I pointed out that the resolution into triplets, &c., which the spectral lines suffer in a strong magnetic field, did not appear to follow any obvious general law, but appeared to be some complex function of the wave-length. To this was added the following remark: "It is possible, however, that the lines of any one substance may be thrown into groups for each of which $\delta\lambda$ varies as λ^2, and each of these groups might be produced by the motion of a single ion. The number of such groups in a given spectrum would then determine the number of different kinds of ions in the atom or molecule.

"Homologous relations may also exist between the groups in different spectra, but all this still remains for complete investigation."

Although this investigation is still far from complete, yet the measurements so far made uniformly go to show that the foregoing expectation is about to prove true, and that e/m or $\delta\lambda/\lambda^2$ is the same for the corresponding lines of the natural groups in the same spectrum, and, further, that this quantity remains the same for corresponding lines or groups in the homologous spectra of different substances.

Not only is the magnitude of the magnetic effect governed by the foregoing law, but the *character* also of the effect is the same for the corresponding lines; and this is very interesting, as it shows that the corresponding lines probably arise from the same origin. The theory is consequently verified by the facts when the spectral lines are considered in groups corresponding to the molecular events which produce them.

THOMAS PRESTON.

COAST-TELEGRAPHS AND SPACE-TELEGRAPHY.

THE year 1898 was an important period in the history of space-telegraphy, it was the period in which the possibility of being able to signal across wide stretches of open sea, with certainty in all weathers and at high speeds, became first generally recognised as practicable. Within the year the final report of the Royal Commission on the question of Coast-Telegraphs, published late in 1897, came into our hands; and the last few months of the year witnessed a truce to the war of "wireless-telegraphy." A wave of good feeling has now united the opponents into something like coherence, and the honours have been divided with universal approval. The result is that for the future Italy takes prominence, England eminence, while Russia, Germany and France share the luxury of many grievances.

The close of the year is very appropriately characterised by three papers, respectively communicated by Dr. Lodge,[1] Mr. W. H. Preece,[2] and Mr. S. Evershed,[3] to the Institution of Electrical Engineers, all emphasising the merits of one and the same system of space-telegraphy. The authors themselves were more or less unanimous as to the course further experiment should take, but the discusssion that followed the reading of these papers showed a certain lack of directness; many of the speakers were carried away by side issues, and a great deal of time was occupied with ill-considered suggestions and old matter. While fully recognising the value of open discussion, and of hints thrown out at random on subsidiary matters, the present writer thinks it may be useful here to indicate the limits to which the problem may be narrowed down, and to point out the very serious work that is now calling for the aid of space-telegraphy.

It is very generally admitted that space-telegraphy will replace metallic-circuit systems only under conditions where metallic circuits are impracticable. The fact that metallic circuits have been laid over the Andes, may be taken as proof that there are remarkably few land-areas that cannot be spanned by wires. For communication between *fixed* points on rough coasts, a wire suitably protected is still the right and the best thing, as is evidenced by the cable[4] laid in 1890 between Pollagill Bay on the north-west coast of Ireland, and Portdown Bay, Tory Island, and thence by duplicate underground cables to the lighthouse on the north side of the island. The great advantage of a metallic-circuit system is the consequent privacy of the messages, the simplicity of the apparatus, the speed of transmission, and the possibility the system offers for working by telephone, and in other ways avoiding the expense of skilled operators. Space-telegraphy is at present limited to comparatively short distances, and its usefulness is confined to spanning estuaries, skirting sea-boards, and for such purposes as

that to which it was applied by Mr. Preece between Oban and Mull in 1895. But, except in rare instances, it is only likely to replace submarine cables between moored vessels and the shore, *e.g.* between light-ships and the coast-guard stations. The point of failure in submarine-cable communication thus happens to coincide with the point of favour of space-telegraphy. The present object of those working at space-telegraphy should therefore be to supplement the cable-system of coast telegraphs, so that all the light-vessels and lighthouses of our coasts may be brought into communication with one another and with the life-boat stations.

Some idea of the scope of the work of completing our coast-telegraphs may be gathered from the fact [1] that the whole number of distinctive lights, including port, harbour, and pier lights, light-vessels, and lighthouses on the coasts of the United Kingdom in October 1898 was 1095, and at the beginning of that year only[2] 51 light-vessels and light-ships were in communication with the telegraphic system. Three additional lighthouses, *i.e.* those at Godrevy, the Skerries, and Walney Island, were connected to the shore during last summer; but pending [3] further results of the experiments with the system of "wireless-telegraphy," it was thought better to postpone the work of connecting moıe light-ships to the shore by electric cables. These lighthouses and other sea-marks are maintained out of the fund [4] derived from lighthouse tolls, which amount to over 500,000*l.*, the lighthouses, &c., being thus self-supporting. This fund has lately been augmented by a special grant; with a view to increasing the efficiency of the system.

The hard task of establishing communication with a light-ship moored in a tide-way, successively rising and falling at each tide, swinging, rolling, and pitching, and in other ways gesticulating around her uncertain anchorage, has taxed the resources of cable engineers for the last quarter of a century. The system now generally adopted consists in the use of a swivel[5] or toggle having a hollow spindle so as to allow a telegraph-cable to be passed up through the middle of it. This swivel is placed between the ship and her moorings at about the water-line. One or more chains lead down from "eyes" on the swivel to the mooring anchors; there are generally two such chains, or there may be three, spread out tripod-fashion, to terminate in mushroom anchors. A riding-chain leads upwards from the swivel, and is secured to the vessel in the ordinary manner after passing through the hawse-pipe; the cable is hauled on board through the hollow swivel, over a sheave and on to a drum, which can be turned round by hand as required, to take the twists or "turns" out of the cable as they are formed. A special veering-drum has been designed by Mr. Benest,[6] by means of which this operation of taking out "turns" is performed automatically by a special gear on the drum. Electrical communication is maintained through the axes of the drum by brush-contacts or otherwise. In rough weather the riding-chain is generally veered out, sometimes up to fifty or sixty fathoms; and after a gale it is often found in tangled masses, which are sometimes as large in girth as that of a man. The cable itself, if it has not been entangled, has meanwhile been saved from kinking by the swivel device, but it suffers a good deal from the threshing and flattening against the bottom, from friction at the swivel, and occasionally from fouling the chains. An ingenious type of veering-cable has been designed by Mr. F. C. Crawford,[7] which is built up in such a way that it is very difficult to make a kink in it. To secure this result, the stranded conductor

of seven-tinned copper wires is covered with india-rubber and lapped with cotton tape to make a bedding for the sheathing wires. The sheathing consists of twelve double-tinned steel wires, each coated separately with india-rubber and tape. Finally there is an outer serving of india-rubber, which encloses everything into a compact form, and, while allowing the requisite amount of flexibility,[1] prevents the sheathing wires from slipping over one another when the cable is bent. As a further protection, especially against the "threshing" action, this veering-cable is occasionally threaded with beads or ferrules of lignum vitæ, or with washers of india-rubber.

Another metallic-circuit method has been tried at Sandy Hook,[2] in which use is made of the mooring chains themselves as a means of connecting a telephone in circuit from the vessel to the cable. This method is reported upon very favourably by its designers, Messrs. Blake and Caldwell, but in their account of it the conditions are not very fully elaborated. The present writer made some experiments in this direction some years ago, and came to the conclusion that the conductivity of such chains was too variable to be trusted. His tests showed that a mooring-chain of 2-inch links and $\frac{1}{2}$-inch iron, 12 fathoms in length, after being pickled in tar, dried, and slung up in the air, had a resistance of 9 megohms when tested with 100 volts; when tested with 750 volts the resistance broke down to 400 ohms. A similar chain, dry and somewhat rusty, had a resistance of 850 meghoms. When dipped in water and again slung up, the resistance of the 12 fathoms was 25,000 ohms. Chains sagging in water were able to transmit telephone currents with a battery of a few volts. Two mooring-chains, of the same dimensions as those described above, were carefully tarred, and the contacts at the links were cleaned bright over a small area. The chains were then paid out from the shore parallel to one another, 8 feet apart, in about 2 fathoms of water in the Thames, the distant ends being hauled on to a barge. Telephoning between the barge and the shore was impossible, even with 100 volts in the circuit. All the electricity passed from chain to chain by way of the water. Brass chains had, of course, much lower resistance than the iron chains; the resistance of brass chains was practically the same, wet or dry. But it was always found that with any chain whatever in the circuit, the loose contacts caused "buzzing"[3] in the telephone. It is possible that Messrs. Blake and Caldwell used chains under great stress, or that they used some special device, but in view of his own experiments the present writer does not regard the chain system as a practicable one.

Some years ago an alternative method of connecting a light-ship to a telegraph cable was suggested by Mr. James Wimshurst. He arranged a swivel which contained two flat coils, a primary and a secondary, placed one over the other, so that one could rotate coaxially upon the other, for the purpose of avoiding kinks as the ship swings about. As a matter of fact, the danger does not depend so much upon the twist, as upon the threshing action due to the rise and fall of the cable. Mr. Wimshurst's suggestion is worthy of a trial, but it must be remembered that the swivel, in the form proposed by its designer, meets only a very small part of the difficulty.

This short review of metallic-circuit and allied direct-cable methods, serves to show that the attempts made in this regard by the Royal Commission have only resulted in partial success.[4] While admitting that the problem is now fair game for the space-telegraphers, the present

1 This cable is in use at Formby Light-ship, with very satisfactory results.
2 Annual Report of the Lighthouse Board of the United States, June 30, 1895.
3 See *Electrical Review*, vol. xxvii. p. 57 and p. 656, 1890; also May 14, 1897.
4 *Standard*, Friday, February 1, 1895: "The Ramsgate life-boat and tug *Bradford* proceeded to the Goodwins, in response to signals of distress from the lightship; the lightship telephone having, it is understood, got out of order."

writer would point out that the resources of cable engineers in devising direct metallic-circuits are by no means exhausted. There is a singular lack of evidence on this point in the Blue Books; the Royal Commission seems to have swung about a good deal on its own small swivel, with something very like disregard for outsiders. For some reason, perhaps unknown, they failed to call as witnesses the very men whose experience would have made for success. In departing from these older methods, it must not be forgotten that we are departing from all the advantages offered by the telephone; skilled operators will have to be requisitioned, and there will be need for a delicate device for "calling-up" the operator.

The fourth Report (dated May 12, 1896) of the Royal Commission concluded with a very hopeful note on a contemplated trial of an "inductive method" suggested by Mr. Evershed. "Under this system," it says, "the cable running from the shore is laid in a circle on the bottom of the sea immediately under the light-vessel, the circle having such an area that the vessel will always be within the circumference of it. Round the deck of the vessel a number of 'turns' of insulated wire are coiled, which are in connection with a telephonic receiver on board ship. This system has not yet (May 1896) been subjected to a practical test at a light-ship."

The fifth and final Report of that same Royal Commission (September 1897), referring to the trial, observes that "the experiment was carried out in August 1896 at the Goodwin (North Sand Head) light-vessel, but after a careful trial it proved a failure. The apparatus had been tested on shore with satisfactory results, but when it was tried at the light-vessel, which is moored in ten fathoms of water, it was found almost impossible to effect communication by means of it, the electric energy being almost entirely lost in the sea. The difficulties experienced were entirely electrical."

In the following year a mathematical investigation as to the cause of this failure was undertaken by Mr. C. S. Whitehead (*Proc. Phys. Soc.*, vol. xv. pt. xi. pp. 188–200, 1897); it was communicated to the Physical Society in a paper read June 11, 1897. His theoretical results show that if his calculations are correct, the normal magnetic induction of the primary coil loses 79 per cent. of its initial value in passing to the secondary through ten fathoms of sea-water. These figures as to the absorption-factor of sea-water have been criticised by Mr. Oliver Heaviside and by Dr. Oliver Lodge. In the meantime Mr. Evershed has turned his attention to improving his apparatus. In his recent paper he regards the inductive coils as a particular case of a dynamo-electric machine, he neglects the absorption-factor, and gives an expression for the power available at the receiving station for ultimate conversion into motion at the receiving instrument. The result arrived at is that the mechanical power is independent of the number of turns into which the total volumes of copper are divided on the primary and secondary circuits, and that the two circuits should have equal volumes of copper. His assumption at the outset, that the use of two horizontal circuits implies a loss of one-half the mutual induction between them, may have to be modified. Perhaps the most important part of Mr. Evershed's paper is his description of a "call" or receiving apparatus, which enables exceedingly minute currents to be detected. From a remark in his paper, he does not appear to be aware of the work that has been done in America by Lucien Blake and Eugene Caldwell in their attempts to provide an instrument to replace the telephone. In the Annual Report of the Lighthouse Board of the United States (June 30, 1895, p. 37) will be found an account of a calling device. This Report says: "The receiving apparatus or relay for this system would be vibratory in character and tuned to a frequency of vibration to correspond with the period of the calling current. In addition to this mechanical adjustment, the electrical circuits might be adapted by the use of condensers and inductances to respond more readily to alternate currents of the same period. The action of such a system would be cumulative, *i.e.* each successive impulse of current would arrive just in time to increase the vibration in the relay until sufficient amplitude would be obtained to operate a circuit-closing device." This report also touches upon an interesting point raised by Sir Henry Mance in the recent discussion. With regard to the sensitiveness of "calls," it observes that "a careful study of all kinds of instruments in which weak alternating currents produce mechanical movement, shows that by far the most efficient are those in which the current does not produce an alternating magnetic field, as in the electrodynamometer, but operates to increase and decrease the strength of field of a permanent magnet. The mechanical motion produced by such polarised machines is always vibratory. Careful measurements in the laboratory show that this relay will work positively with a current representing 0·0001 watt, and that it can be operated with much less energy than this." This report seems to have escaped the attention of Mr. Evershed; he suggested in his recent paper that so far as he was aware the ordinary Bell telephone has been exclusively used as the receiving device in this class of experiments. There is, of course, no question as to priority; Mr. Evershed was using a vibratory indicator on this synchronous principle in 1892, the American report refers to an instrument designed in 1895. In his latest (1896) form of apparatus, Mr. Evershed duplicates the vibratory metallic rectangles; they are connected to two separate secondary circuits in such a direction that they oscillate in opposite phases in a strong magnetic field. This arrangement has the advantage that when the twin rectangles are in unison it is almost impossible to bring them into contact by shaking the instrument.

Mr. Preece's paper is a history of the experiments made by himself and his staff, since 1885, on "the electromagnetic form of ætheric telegraphy," *i.e.*, on the method of signalling between one alternate current circuit and another. This work has been more or less familiarised to us by the newspapers. He used horizontal coils of large diameter at the sending and receiving stations, but they were regarded as "impractical things" and they were replaced by straight conductors, placed in parallel planes, one at each station. Capacity and self-induction were eliminated. An interesting series of experiments is described, in which two earth-plates are buried at a distance apart in the earth; the lines of electric "flow" are traced, and the locus of a hypothetical resultant-conductor is plotted. Incidentally, Mr. Preece makes the curious statement that "we know *by Ohm's law* that the resistance of a circuit increases with its specific resistance and length, and diminishes with its sectional area." By Boyle's law this involves a misconception! Of the various arrangements of inductors for his mode of signalling, Mr. Preece prefers parallel wires connected to earth at each extremity, the wires being carried to a considerable height. The most satisfactory results were obtained over a distance of 3·3 miles across the Bristol Channel; and when it is remembered that the speed of signalling is practically as high, and that the system is as certain and as efficient as the ordinary metallic circuit system, this result must be regarded as the best so far brought to notice.

The question naturally occurs to us at this point, What then has become of the "coherer" systems? Mr. Preece[1] has recently said that the Marconi system is able to traverse a distance of twenty-five miles; but on the same occasion he mentions that there would be no difficulty in communicating by the alternate-current inductor system over a similar distance. Hence there

[1] *The Engineer*, November 25, 1898.

is little to choose on the merit of distance. On the other hand the speed of signalling by the "Marconi" system is limited to something like twelve words a minute, and we must conclude that it is this circumstance that handicaps the method. It is also probable that "coherer" systems are at present too susceptible to mechanical and fortuitous electrical tremors for the ordeal of a telegraph office, but in the absence of evidence it is perhaps scarcely fair to draw comparisons in this regard. According to the *Times* of Monday, the 9th inst., arrangements are being made under the direction of Signor Marconi at the South Foreland lighthouse, and aboard the South Goodwin light-ship, for a series of experiments with his apparatus. It is stated that if the system is found satisfactory it will forthwith be adopted between those points —the distance between them is about three miles.

Two articles in the *Electrician* of November 12, 1897, one by Dr. Lodge[1] and the other by Mr. A. C. Brown, should be referred to as indicating the extent of the work done and the hopefulness of the votaries of "coherer" systems at that time. Later developments of the "coherer" system, particularly in the matter of syntony and the best arrangement of contacts, are dealt with by Dr. Lodge in a communication to the Physical Society of January 21, 1898, an account of which appeared in NATURE in February 1898. The possibility of individualising signals by syntony on Dr. Lodge's system is discussed in an excellent article in the *Electrical Review* of August 19, 1898, which is prefaced by some remarks that already show the weak points of "coherer" systems. Messages had then been sent by Marconi over a distance of about sixteen miles, and received in "dot and dash" on the Morse ribbon at a rate of something under twelve words a minute; but it had been found in practice that the principle of resonance could not be applied with sufficient effect to ensure that messages should be recorded only by a single selected receiver. Whether the later more elaborate methods of syntony for "coherer" systems, proposed by Dr. Lodge, have justified themselves in practice is not yet known, but it is a significant fact that Dr. Lodge's most recent paper on the subject of space-telegraphy makes a distinct departure from the "coherer" system, and contains no account of experiments in the direction of syntonised receivers used in this particular way.

In 1898, experiments as to the mysterious connection between "coherers" and photo-electric phenomena made little progress towards a practical system of telegraphy. In the hands of Prof. Minchin these experiments, at the outset, showed great promise; they gave us the "collecting wire" which, protruding into space, acts as a "feeler" for Hertz waves, but at present they remain as toys of the laboratory. The so-called "Lichtelektrische Telegraphie" of Prof. Zickler, of which a very good account is given in the *Elektrotechnische Rundshau*, No. 21, pp. 232-233, 1898, is more pretentious as a means of signalling. Prof. Zickler makes use of an old discovery, due to Hertz, that ultra-violet light is able to reduce the spark-resisting power of an air-gap. He directs a beam of light from an arc lamp, provided with a shutter, upon the extended spark-gap of an induction coil, and by opening and closing the shutter causes sparks to pass at the gap at corresponding intervals of time. These sparks affect a "coherer" circuit, and signalling is rendered possible. Such experiments are very attractive from a purely scientific standpoint, but it is not easy to see the advantage of this method as compared to the ordinary heliograph. Using the simplest form of apparatus, Prof. Zickler succeeded in signalling by this means across a space of two metres; and by the aid of an arc lamp that expended nearly two horse-power, and by the use of quartz lenses, that distance was extended to 200 metres. The speed of receiving the signals is not mentioned; the extreme limit is probably about twelve words a minute. He proposes to apply the system to lighthouses and to fortresses. We admit that such a system would be admirably suited for the purpose of warning our *foes* off dangerous parts of the British coasts; but for the purpose of warning our own or friendly ships, a surer means of communication must be adopted.

[1] By a slight error, Dr. Lodge there attributes an experiment on liquid "coherers" to Lord Rayleigh. This experiment was first described and shown by the present writer on March 26, 1897, at the Physical Society. A few weeks later it was *repeated* by Lord Rayleigh at the Royal Institution.

Comparing the various methods,[1] and keeping in mind that we are here concerned with a practical question for engineers, rather than with the scientific aspect of space-telegraphy, it would seem that the "coherer" systems as a whole are about to be cast aside, and that preference is to be given to alternate-current inductor systems for coast-telegraphs. If this is indeed to be the case, the problem is greatly simplified, and experiment resolves itself into the single task of finding the best design of apparatus for communicating between a moored light-ship and the shore by means of inductor coils. Dr. Lodge's paper on "Improvements in Magnetic Space Telegraphy" gives us what may be regarded as the academical aspect of that task; he describes a new receiving device for magnetic induction telegraphy, and he explains the method of putting it into practice. The principal feature of this device is the outcome of an electric resonance experiment first described in NATURE, vol. xli. p. 368, eight years ago—namely, the experiment of syntonic Leyden jars. Dr. Lodge now replaces the jars by condensers, and the "tuned circuits" take the form of horizontal coils of wire. The inducing coil is connected to an alternate-current dynamo, and the induced coil is connected to a train of telephone relays, the last of which is thus set into violent action at each received impulse. The paper includes the theory of two such circuits arranged in mutual syntony, and it is full of information and suggestions as to the proper course future experiment should take; the advantage of syntony is discussed, and the relative importance of conduction and induction is considered together with a detailed investigation of the theory of "detectors" for such a system.

The absorption-factor in the case of sea-water will probably be one of the first matters to be dealt with by experiment and theory in the present year. By the use of horizontal inductor coils, one on the light-ship and one ashore, Dr. Lodge avoids the practical difficulty; nevertheless the problem is sure to elicit his interest. Mr. Whitehead, holding tacitly to Maxwell's equations, deduces a law for the absorption-factor, and to this law Dr. Lodge takes exception. Maxwell supposed that the total current was made up of the polarisation current and the induction current; Mr. Whitehead assumes that the polarisation current may be neglected, and that provided the frequency is not comparable with that of light, no serious error can arise from that assumption. Do Maxwell's equations fail then for such a case? Dr. Lodge seemed unwilling to admit that they do fail; he suggested that Mr. Whitehead had written them down in a form that did not agree with Maxwell, and that Prof. J. J. Thomson had written them in yet another form. Mr. Whitehead now asks Dr. Lodge what is the right form? And that's how the matter stands.

ROLLO APPLEYARD.

THE FISHES OF TANGANYIKA AND OTHER GREAT LAKES.

THE first part of the fifteenth volume of the *Transactions* of the Zoological Society of London, which has just been issued, is devoted to a report by Mr. G. A. Boulenger, F.R.S., on the collection of fishes made by

[1] For the various methods of space-telegraphy, see a paper by Dr. S. P. Thompson (*Soc. Arts Journal*, 46, pp. 453-460, 1898.

Mr. J. E. S. Moore in Lake Tanganyika during his recent expedition to Eastern Africa. As Mr. Moore has shown in our columns (NATURE, vol. lviii. p. 404), there are two faunas in Lake Tanganyika, the normal fresh-water, and what Mr. Moore proposes to call the "Halolimnic" group, the latter being evidently of marine origin. That this is the case has been conclusively shown by Mr. Moore's studies of the splendid collection of molluscs which he obtained in that lake. It would therefore be naturally expected that the results of the examination of Mr. Moore's fishes, which has been undertaken by Mr. Boulenger, would likewise show the presence in Lake Tanganyika of a certain number of "Halolimnic" or marine fishes. This, however, does not prove to be the case. Mr. Moore's fishes, Mr. Boulenger informs us, do not yield any such startling results as the mollusca and other invertebrates. The fishes of Tanganyika, though very novel and very remarkable, do not embrace any marine forms. This may be due, as Mr. Boulenger observes, either to the origin of the present fish-fauna not reaching as far back in time as that of the molluscs, or to the incompleteness of Mr. Moore's series. The latter explanation is probably the correct one, as Mr. Moore met with great difficulty in dredging in the deeper water of Tanganyika, only one fish having been obtained from a depth of about 400 feet. This (*Bathybates ferox*), although of a new genus and species, belongs to the widely-spread African family Cichlidæ.

Altogether, the fishes obtained by Mr. Moore in Lake Tanganyika are referred by Mr. Boulenger to thirty-five species, belonging to the families Serranidæ, Cichlidæ, Mastacembelidæ, Siluridæ, Cyprinidæ, Characinidæ, Cyprinodontidæ and Polypteridæ. It would thus seem that in general characters the Tanganyikan fish-fauna, so far as it has been yet ascertained, does not materially differ from the fish-faunas of the other great African lakes, but that most of the Tanganyikan species and many of the genera are distinct, the family Cichlidæ alone having furnished types of ten new genera in the present collection.

In his introductory remarks to the present memoir, Mr. Boulenger has taken the opportunity of putting together lists of the fishes already known to be found in Lake Nyasa, Lake Tanganyika, Lake Victoria and Lake Rudolph. From the first of these we are now acquainted with thirty-seven species, from the second with forty-three, from the third with only nineteen, and from the fourth (Lake Rudolph) with only nine. These lists, Mr. Boulenger points out, must be taken as giving a very inadequate idea of the piscian inhabitants of the great African lakes, owing to the manifest incompleteness of the collections upon which they are based. Of the other lakes nothing whatever, unfortunately, can be said at present, only one species of fish having been yet brought from the great Albert Nyanza. It is evident, therefore, that there is a fine field for the enterprising ichthyologist in the great African lakes.

PROFESSOR ALFREDO ANTUNES KANTHACK.

BY the death of Prof. Kanthack the science of pathology has lost one of its ablest and most indefatigable exponents, and the University of Cambridge, for the second time in less than fifteen months, a brilliant occupant of its chair of Pathology.

At the closing meeting of the Pathological Society, last summer, it was noticed by several of Prof. Kanthack's friends that he appeared to be less energetic and vigorous than usual. After this the work of the long vacation appears to have told upon his health so seriously, that even during the course of a short holiday it was remarked at the opening of the Pathological Laboratories at Liverpool that he still appeared to be far from well. In spite of this few were prepared to learn, about the middle of December, that Prof. Kanthack was suffering from a malignant growth, the symptoms of which had first been indicated by jaundice and severe abdominal pain—a diagnosis that was afterwards confirmed. He died on December 21, 1898.

Alfredo Antunes Kanthack was the second son of Emilio Kanthack, Pará, Brazil, and Victoria his wife, both born in Pernambuco. He was born at Bahia on March 4, 1863, and spent the first few years of his life in Bahia and Ceará, Brazil. He was brought to Germany in 1869, being placed under the care of Pastor Hoppe of Artlenburg on the Elbe, father of the present Prof. Edmund Hoppe of Berlin. In 1870 he was sent to Hamburg, where he was first taught by a strict disciplinarian, "a tyrannical pedagogue but excellent teacher of elementary subjects." During this period he is described as "being by no means brilliant but extremely diligent." Early in 1875 he went to school in the Wandsbeck Gymnasium, near Hamburg. In 1876 he was transferred to the Gymnasium of another Prussian Government school at Lüneburg, and in 1878 to the Gymnasium at Gütersloh, where he greatly distinguished himself. In 1881 he came to Liverpool, where his parents were then residing, and continued his studies for a short time in the Shaw Street College (Classical Department). In 1882, after passing his University of London matriculation examination, he commenced his arts curriculum, and continued his studies in science and medicine under Mitchell Banks, Caton, Mott and other well-known teachers of the Liverpool medical school, graduating B.A. in 1884, B.Sc. in 1886, M.B. and B.S. (in each instance with honours), F.R.C.S. Lond. in 1888, and M.D. Lond. in 1892; whilst in 1897 he proceeded to the degree of M.A., and became a Fellow of the Royal College of Physicians, London. After completing his medical curriculum Dr. Kanthack, in 1889, proceeded to Berlin, and there, as part of the result of his studies under Virchow and Krause, he contributed an admirable paper to Virchow's *Archiv* on the histology of the larynx, a paper which at the time gave rise to a lively controversy, Dr. Kanthack maintaining his original thesis with marked ability and success. Whilst in Berlin, too, he worked under Koch, and here, as in the pathological laboratories, he attracted the attention and received the special encouragement of his teacher. Shortly after his return from Berlin, and probably as the result of an expression of opinion on the part of his teachers—Virchow and Koch—he was appointed one of the Special Commissioners along with the late Dr. Beaven Rake and Dr. Buckmaster, by a joint Committee of the Royal College of Physicians, the Royal College of Surgeons and the Executive Committee of the National Leprosy Fund, to investigate the prevalence, the pathology and the treatment of leprosy in India.

In 1891 Dr. Kanthack was appointed John Lucas Walker Scholar under the late Prof. Roy, and in succession to Dr. William Hunter. During the time that he held this scholarship in Cambridge, he published, along with Mr. Hardy, a paper on the wandering cell in the mammalia, in the *Journal of Physiology*, and a paper on the behaviour of wandering cells, in the *Proceedings* of the Royal Society, vol. lii. These papers are of special importance as indicating that, although thoroughly acquainted with Metschnikoff's work and all that that author had to advance in support of his phagocytic theory, Dr. Kanthack had made, during his stay in Germany, an accurate forecast of the destination to which the work that was being carried on in Germany by Koch's pupils

would eventually lead. During this period, too, he carried on an investigation on Madura Foot, and compared mycetoma with actinomycosis; this paper appeared in the *Journal of Pathology* and in the *Transactions* of the Pathological Society. In 1892 Dr. Kanthack became medical tutor at the Royal Infirmary, Liverpool, and in order that his bacteriological training might be utilised, a special demonstratorship of bacteriology was founded for him. The following year the authorities at St. Bartholomew's Hospital retained Dr. Kanthack's services as director of the Pathological Department in the School and Hospital and Lecturer on Pathology and Bacteriology; and a year later gave him the appointment of Curator of the Museum. In addition to the teaching and routine work of this period he contributed numerous notes and observations to the *Transactions* of the Pathological Society, and, probably for the purpose of systematising his teaching work and saving time in the explanation of details, he in 1894 published, in conjunction with Dr. Rolleston, a "Manual of Practical Morbid Anatomy"; and in the following year, along with Dr. Drysdale, a work on "Practical Bacteriology." Both these works give evidence of wide reading and of an accurate knowledge of literature thoroughly up to date. When Prof. Roy became so ill that it was evident that he could no longer carry on his professorial work, and in all probability would never again be able to take up the duties of his chair, Dr. Kanthack was appointed Deputy Professor of Pathology. The work of this post he carried on simultaneously with his duties at St. Bartholomew's Hospital, making the return journey between London and Cambridge several times a week. This, for a man who, a short time before, had recovered from a severe attack of typhoid fever, involved a very great physical strain; and early in 1897 Dr. Kanthack resigned his post at St. Bartholomew's and gave undivided attention to his work in Cambridge, where, on Prof. Roy's death, he was appointed Professor of Pathology.

Of Prof. Kanthack's influence on the study of pathology and bacteriology in this country, it is as yet too early to speak, though there can be little doubt that, apart from the work that he himself initiated, that of his pupils must ultimately leave a deep impress on the scientific medicine of our time and that immediately to follow. In many ways Prof. Kanthack was an ideal teacher. He exerted great personal influence over the young men who were brought into contact with him. His reading was very wide, so that, possessing a retentive memory, he was able to store up an enormous amount of accurate information which he could always bring to bear on the work that he had in hand. He was thus able to make a profound impression on his pupils. He had a sufficient amount of dogmatism in his manner and method to inspire them with confidence in his teaching, and to give those who were looking to him for guidance a sheet-anchor to which they might hold until they were thoroughly able to take their bearings for themselves. From his extensive reading, too, which, as already indicated, was always kept well up to date, he was able to determine at once what special points remained to be worked out in connection with the various subjects occupying the attention of the scientific world; whilst his keen critical faculty enabled him to mark the flaws in experiment or argument in published work that came under his notice, so that he was always able to set his pupils on to work which should shed some new light on the various questions attacked, and to gather facts and information which would help him in the solution of the problems on which he himself was engaged. Those of his pupils who knew him best regarded him with feelings of the deepest affection—to them the loss is intensely personal. In 1895 Prof. Kanthack married a Liverpool lady—Miss Lucie Henstock—the daughter of the late John Henstock, Esq., of Liverpool.

NOTES.

IN retiring from the presidential chair of the Paris Academy of Sciences, at the meeting on January 2, M. Wolf referred to the changes which had occurred in the list of members and correspondants during last year. In the section of geometry, Prof. Cremona was elected correspondant in succession to Prof. Brioschi. The section of astronomy lost M. Souillart, and the two vacancies caused by his death and that of Dr. Gould, have not yet been filled up. There is a vacancy in the section of geography and navigation, caused by the death of M. Manen, and also a vacancy in the section of chemistry, caused by the death of Prof. Kékulé. In the section of mineralogy, M. Depéret was elected to succeed the late M. Pomel, and Prof. Marsh to succeed the late Prof. Hall. There are two vacancies in the section of botany, one caused by the death of Baron von Mueller. The section of rural economy has lost Marquis Menabrea and M. Demontzey by death, and the vacancies have not yet been filled up. Two vacancies also exist in the section of anatomy and physiology, on account of the deaths of Prof. Lovén and Prof. Steenstrup. In the section of medicine and surgery Prof. von Leyden has succeeded Prof. Virchow, who has been elected foreign associate of the Academy; and Prof. Mosso has succeeded the late Prof. Tholozan.

THE Council of the Royal Institute of Public Health have awarded the Harben Gold Medal for 1899 to Lord Lister, P.R.S., in recognition of his eminent services to preventive medicine. Prof. William R. Smith, who has been appointed Harben Lecturer for the year 1899, has chosen "Diphtheria" as the subject for his lectures.

A REPORT has reached us from Mr. L. Small, of Denver, of the discovery of a huge fossil Dinosaur that must have been about 130 feet in length. The remains were found by Prof. W. H. Reed, of Wyoming, in Jurassic strata, near Laramie, and indicate an animal much larger than any form that has been previously obtained.

IN addition to the New Year honours referred to last week, Sir Charles Cameron, medical officer of health for the City of Dublin, has had the Order of C.B. conferred upon him.

FATHER RODRIGUEZ DE PRADA has been appointed director of the Vatican Observatory.

THE annual general meeting of the Royal Meteorological Society will be held on Wednesday next, January 18, when the report of the Council will be read, the election of Officers and Council for the ensuing year will take place, and the President (Mr. F. Campbell Bayard) will deliver an address on "The government meteorological organisations in various parts of the world."

ON Tuesday next (January 17), Prof. E. Ray Lankester delivers the first of a course of ten lectures at the Royal Institution on "The Morphology of the Mollusca." On Thursday (January 19), Mr. A. Savage Landor will begin a course of three lectures on "Tibet and the Tibetans." The Friday evening meeetings of the members will commence on January 20, when Prof. Dewar will deliver a discourse on "Liquid Hydrogen."

THE ninth International Congress of Ophthalmology will meet at Utrecht from August 14 to 18. Only the English, French, and German languages will be employed. There will be three sections—one for anatomy, pathological anatomy, and bacteriology; one for optics and physiology; and one for clinical and operative procedures. There will be a secretary for each language as follows: English, Dr. A. McGillivray, Dundee; French, Dr. A. Dufour, Lausanne; German, Dr. A. Siegrist, Bâle.

BY making use of the exceedingly low temperatures that can now be obtained, a very simple method for exhausting X-ray and other vacuum tubes presents itself. An example of this was given by Prof. Dewar at a recent meeting of the Royal Society, at which he was able to produce an almost perfect vacuum. By dipping the end of a closed tube filled with air into liquid hydrogen, the air quickly condensed at the bottom in a solid form. It then only remained to separate from the rest that part of the tube from which the air had been so removed, by heating and sealing off, and the tube was found to possess an extremely high vacuum. In fact, so perfect was the vacuum that it was difficult to pass an electric current through it. One great advantage of this mode of procedure is that in the above case only one minute was taken to obtain the required result.

WE regret to see, in the *Electrical Review*, the announcement of the death of Dr. Eugen F. A. Obach, at the comparatively early age of forty-six years. He was born in Stuttgart, of Swiss parents. In 1875 he obtained his degree of Doctor of Philosophy at the University of Leipzig. After spending a few years in electrical engineering, Dr. Obach devoted himself mainly to the study of the chemistry of gutta-percha and india-rubber, the result of his extensive and varied knowledge of these substances being embodied in his Cantor Lecture delivered before the Society of Arts. A long abstract of these lectures appeared in NATURE in June last (vol. lviii. p. 136). Shortly after that time his health failed, and even prolonged rest from work brought about no improvement, and he died on December 27 at Graz, Styria. Dr. Obach had been a frequent contributor to the literature of electrical science since 1875, about a score of papers being published in the English and German technical journals or in the *Proceedings* of scientific societies.

DR. REINHOLD EHLERT, distinguished by his studies in seismology, has lost his life by an Alpine accident on the Susten Pass. Among other valuable seismological works, he wrote a treatise on "A comparison, explanation, and critical estimate of the most important seismometers, with special reference to their practical utility." This work was *couronné* by the philosophical faculty of the University of Strasburg, where Dr. Ehlert conducted his investigations.

REUTER reports from Copenhagen that Captain Daniel Brunn has decided to organise an expedition next summer to search for traces of Herr Andrée and his companions in the neighbourhood of Eastern Greenland. The expedition will start from the east coast of Iceland, and proceed by way of Jan Mayen Island to the vicinity of Cape Barclay, on the East Greenland coast.

THE *Pharmaceutical Journal* reports the opening of a chemical and pharmaceutical laboratory in Rajkote, the seat of the Government in the province of Kathiawar, Western India. The building is the gift of Azam Laxmon Meram, who contributed 30,000 rupees for its construction; and its equipment has been provided from the State Joint Fund. The object for which the building has been primarily founded is for improving the practice of native medicine and for making known valuable Indian remedies to Western science, and also to ascertain which native herbs may be made more adaptable to science; and it is hoped that eventually it may further the progress of bacteriology and sanitary science. The director of the laboratory is Mr. H. L. Lee.

THE present position of the Rontgen rays in military surgery was described by Major J. Battersby in a paper read before the Röntgen Society on Tuesday. Major Battersby was selected for service in charge of the Rontgen ray apparatus in the Sudan, where the temperature varied from 100 to 122 degrees F. in the shade; and his paper was based upon his experience in this campaign. After the battle at Omdurman 121 British wounded were conveyed to the surgical hospital at Abadieh. Of that number there were 21 cases in which the bullet could not be found, or its absence proved by ordinary methods. In 20 out of these 21 cases an accurate diagnosis was arrived at with the help of the rays, the odd case, who was suffering from a severe bullet wound in the lung, being too ill for examination at the time. The senior medical officer in charge of the hospital said:—"The Röntgen rays proved of invaluable assistance in localising the exact position of bullets, and in many cases rendered probing of wounds unnecessary. . . . In many cases the X-rays prevented much suffering to the patient, which would have been caused by probing, the use of the finger, or enlarging the wound in the ordinary search for the bullets, as the skiagraph at once indicated the exact position of the bullet. In other more complicated cases the Mackenzie-Davidson method localised the exact position of the bullet, so that the surgeon was at once able to come to the conclusion if operative interference was judicious or otherwise. If considered advisable, the removal of the bullet was much facilitated by the diagram previously indicating exactly where the projectile was to be found." With regard to apparatus, the most serious difficulty at present is the best method of generating the primary electrical current for charging the storage batteries, or working the coil direct. Primary batteries, for many reasons, are unsuitable and not to be recommended. In the Sudan a small dynamo, driven by means of a tandem bicycle, answered admirably, and was readily transported by rail and river to Abadieh; but as at present constructed, it is unsuitable for mule, camel, or human transport. An ideal apparatus would consist in a statical or friction machine, some modification, for instance, of Mr. Winshurst's, by which the focus tube could be excited direct. In such a design many physical difficulties will occur, but they are not insurmountable. If it is achieved, it will enable the present apparatus to be reduced very considerably by dispensing with primary and storage batteries, dynamos, bicycles, and induction coils.

WITH reference to the landslip from the Sasso Rosso, which destroyed several buildings at Airolo on December 27, 1898, the Zürich correspondent of the *Times* states that Swiss geologists are of opinion that the landslip is by no means over, and that a mass of rocks equal to that which fell last week has yet to come away. It is hoped that the detachment will take place in smaller masses, and that no slip exceeding the present (400,000 cubic metres in volume) is to be apprehended. The summit of the Sasso Rosso is 2300 metres above the sea level, and 1200 above Airolo, and the falling rocks reached the village with a velocity of 15 to 20 metres per second. The present danger lies in the rocks which remain suspended on the flank of the mountain. Should these give way, the village and the southern exit of the tunnel would be endangered by the avalanche, a risk which is increased by recent heavy rain and snow. Compared with other similar avalanches, the amount of débris already fallen is not excessive; at Elm the fall exceeded 11,000,000 cubic metres, at Goldau it was 25,000,000, and the historic landslip at Brienz in 1749 was estimated at 50,000,000 cubic metres.

THE New York Zoological Society has issued the third number of its *News Bulletin*, in which the progress of the work of transforming South Bronx Park into a Zoological Park is described and illustrated. Seven months ago the New York Zoological Park was a tract of wild land, but since then several of the animal houses have almost been completed, and other enclosures have been made. New York City has voted 30,000 dollars as a maintenance fund for six months, both for the care of the animals and the care of the Park, and is expending 62,000 dollars in the development of roads, walks, drains, and other ground improvements. It is a matter for congratulation that

the Zoological Park appears to have become one of the established institutions of the City of New York. The magnificent site, and the fine buildings and enclosures which will eventually be erected upon it, will give the people of the metropolis of Greater America reason to be proud of their Zoological Park.

DR. ROBERT MUNRO writes to the *Glasgow Herald* with reference to the archæological remains recently discovered in the estuary of the Clyde (see NATURE, vol. lviii. p. 488), and with which his name has been associated. He desires it to be known that he does not endorse the opinions that have been promulgated as to the age, structure, and marvels of the Dumbuck crannog, for he regards it neither as a pile-structure nor as a monument of Neolithic times.

THE curator of the Perak Museum at Taiping reports in the Blue Book on the Straits Settlements (C-9108 of 1898) that the museum is now overcrowded, and that there is consequently much difficulty in arranging the collections in their natural sequence, while there is practically no room for new specimens. The Taiping collections are specially rich in the ethnological and mineralogical branches, and the zoological specimens have recently been greatly improved. The photographic and botanical branches were extended during the year, and the museum now contains a valuable section allotted to economic botany. Investigations were carried out, with satisfactory results, on the subject of insects attacking coffee, rice, and other agricultural products, and some experiments were made in connection with tapping rubber. Discussion has been going on as to constituting the museum at Taiping a central museum, supported by all the Federated Malay States. The curator at Taiping suggests that local museums, of which one has been in existence for several years in Selangor, and which, it is to be hoped, will soon be established in the other States, might either be affiliated to, or form branches of, the Federal museum. On the other hand, the British Resident at Selangor urges that the existence of a local museum creates and sustains in the minds of the community an interest in local products, their sources and uses, which cannot fail to be beneficial and deserving of encouragement, and it cannot be argued that people in Selangor or the Negri Sembilan will obtain any advantage from a museum in Perak, however complete, which few of them will probably ever see.
